Signs of trouble have already surfaced. Last week (19 March), the chairman of British Telecom, Sir George Jefferson, was complaining to an audience of equipment manufacturers that development is being hampered by the lack of capital. The complaint is all too familiar. Even in prosperous times, British governments have been unwilling to let the most buoyant of the nationalized industries modernize its network as quickly as technology would allow. When, as now, the cornerstone of financial policy is to keep a tight rein on public expenditure and thus on the need to borrow from the money markets, and when such funds as can be borrowed are increasingly being used to support industries (private as well as public) in danger of collapse, the pressure on British Telecom is greater than ever. The irony is that the investment even of publicly borrowed funds in the telecommunications network would be profitable, which is more than can be claimed for the other investments of borrowed money which the British government has in the past few months felt bound to make in British Steel, British Shipbuilders and British Leyland. As luck will have it, the continuing restrictions on British Telecom's freedom to borrow capital have now been sharpened because its own revenues have risen less quickly than expected, chiefly as a consequence of the recession. The result will be that British Telecom will have to cut back its already modest plans for development in the next two years. Some years from now, when the recession is eventually ended, Britain will be less well endowed with telecommunications than it could have been. The effect of government policy is thus to starve the future so as to feed the past.

But is not this impediment to the proper development of a communications network merely an unfortunate but unavoidable consequence of the recession? That is the simple response to Sir George Jefferson's plea that British Telecom should be liberated from the shackles that now bind it. The calculation is misleading. Can it ever be wise for a government playing entrepreneur to make unprofitable investments while refusing to invest in profitable projects? For private investors, that would be a path to bankruptcy. For governments, good sense is habitually clouded by political considerations. The British government has been investing in steelmaking, shipbuilding and the manufacture of motor cars in part because it cannot bring itself to face the social upheaval that the collapse of these traditional industries would cause in the parts of the United Kingdom in which they are concentrated. Unemployment, the government seems to have decided, is high enough already. So, too, it is. But to fail to invest in potentially productive enterprises such as telecommunications will entail that, when the recession eventually drags to an end, high unemployment will persist for longer than would otherwise be necessary.

How, in these circumstances, can the British government arrange for the development of the telecommunications network at the pace that technology will allow? For the government, the question does not come out of the blue. Sir Horace Barlow, Sir George Jefferson's predecessor at the Post Office, resigned a year ago because the Department of Industry would not agree to his proposal that the development of the telecommunications

network should be financed by allowing the Post Office to borrow some of its capital requirements from private sources. The Treasury with a simple logic insists that any debt that is ultimately guaranteed by the public purse must be counted as public borrowing. But there are ways round this over-simple rule, some of them already embodied in the Post Office Bill now before the House of Commons. For one thing, to the extent that the shading of the public monopoly will make it possible for the first time (in Britain) for terminal equipment to be purchased by private users and not purchased and leased to users by the monopoly, there is scope for reducing the public cost of telecommunications development. But the bill also includes the delphic provision that British Telecom will be allowed to borrow money from private sources for joint enterprises with private industry in which it does not have a controlling interest. In principle, these arrangements would allow expensive capital projects, the use of earth satellites within the telecommunications network for example, or the development of novel kinds of trunk transmissions routes, to be financed privately and then leased back to British Telecom. Precisely such a device is being considered by the British government as a means of allowing the British railways to be electrified without undermining forecasts of public borrowing in the years ahead. So why, while complaining at the chains that bind it, does not British Telecom point to the ways in which its own development could lighten the government's need to borrow money?

The explanation is straightforward but not creditable. Neither British Telecom nor the Department of Industry appears as yet to have adjusted to the opportunities provided by the shading of the public monopoly on telecommunications. While rightly urging that the pace of development in telecommunications should be faster — much faster — British Telecom seems not to have learned that it cannot do everything itself. If, however, its interest is the rapid development of a modern telecommunications network, it should welcome the chance of having as much as possible of the financial burden carried on other shoulders. It should, for example, welcome the prospect that it may no longer be required to buy terminal equipment from manufacturers simply so as to lease it on to users, tying up capital in the process. In practice, British Telecom has taken a much more defensive line, and is clearly planning to compete as fiercely as it can with such of the suppliers of terminal equipment as the Department of Industry may license in the fullness of time. Moreover, as the bill is now drafted, there is nothing to ensure the new monopoly will compete with upstart suppliers on terms that are objectively fair. Indeed, there is a danger that British Telecom will try to beat off the new suppliers to the network by devoting too much of its own resources to its first essay in competition, thus further hampering its capacity to invest in long-term developments. In the circumstances, British Telecom's pleas for more freedom to borrow money sound more hollow than intended.

The solution must lie with the government, the only participant in the reorganization of the British telecommunications network which has an interest that the old monopoly should be eroded and also that the development of the network should be less dependent on public borrowing. Unfortunately, the Department of Industry cannot ensure that British Telecom behaves sensibly while it has assumed for itself the role of final arbiter on trivial technical questions such as the specification and design of the terminal equipment that may be attached to telephone circuits. What is needed, even at this late stage, is that the British government should step back from the day to day regulation of the telecommunications network, delegating that responsibility to a less partial body able to take a judicial view of what constitutes fair competition between British Telecom and the rest of the telecommunications industry. Such devices have been found necessary elsewhere, in the United States for example, in striking a balance between the public interest and those of public monopolies. For the British government, and for British Telecom, the prize would be some relief from the problem of financing a technological development of great promise in the middle of a recession.

DNA guidelines for further attenuation

NIH to consider new voluntary provisions

Washington

Two prominent members of the National Institutes of Health (NIH) Recombinant DNA Advisory Committee (RAC) are suggesting a major transformation of the guidelines covering recombinant DNA research which would not only significantly reduce containment levels for a variety of experiments, but also convert the guidelines into a non-regulatory "code of standard practice". Dr Alan Campbell of Stanford University and Dr David Baltimore of the Massachusetts Institute of Technology claim that revoking the mandatory aspects of the guidelines is compatible with the experience gained since they were introduced five years ago.

The recommendation from Dr Campbell and Dr Baltimore will be discussed at next month's meeting of RAC. Also under consideration will be some less radical proposals suggested at a recent meeting of the chairpersons of local biosafety committees (*Nature* 288, 529, 1980), focusing primarily on reducing the paperwork involved in registering experiments conducted at the minimal P1 containment level, which is expected to receive the committee's support.

In a letter to Dr Donald Fredrickson, director of NIH, the two authors claim that since 1976, when the guidelines were introduced, neither experimental evidence nor theoretical arguments have been put forward to support the argument that recombinant DNA research poses any danger to human health. According to their proposal, the list of prohibited and exempt experiments would be retained, as would RAC. But all mechanisms which have been set up to enforce the guidelines as regulations — including, presumably, local institutional biosafety committees — would no longer be required.

Dr Campbell and Dr Baltimore argue that singling out some classes of experiments as needing higher levels of physical containment has been made at the cost of discouraging variety and innovation and thereby limiting access to useful knowledge. In contrast, they say, "the benefit is likely to be zero".

If NIH agrees to move in this direction, it is likely to proceed cautiously. At the last RAC meeting in January, the committee approved by nine votes to eight, with three abstentions, a proposal from Dr Winston Brill of the University of Wisconsin that the guidelines be changed to permit

recombinant DNA experiments using nonpathogenic prokaryotes and lower eukaryotes to be conducted at P1 containment.

However, in a notice published recently in the *Federal Register*, Dr Fredrickson says that in the light of the closeness of the vote, he is accepting in preference a compromise proposed by another committee member, Dr Susan Gottesman, which would allow the Office of Recombinant DNA Activities to lower containment levels for such experiments on a case-by-case basis, but without requiring RAC review.

One effect of the proposal of Dr Campbell and Dr Baltimore would be to throw into greater prominence suggested safety guidelines for microbiological and biomedical laboratories prepared by the Center for Disease Control (CDC) — which, like NIH, is part of the Public Health Service. However CDC itself has become a recent focus of controversy, following its publication last autumn of an updated draft of what it calls a "national code of practice".

The document, which has been widely circulated to universities and other research laboratories, is divided into two principal sections, and it is the second

section which has generated the most detailed criticism. This contains proposals for treating several types of organisms in a way which many microbiologists feel would be overly restrictive — in particular using viruses such as SV40. As now written, the guidelines "would put most virologists out of business" says Dr Harlyn Halvorson, chairman of the public and scientific affairs board of the American Society for Microbiology (ASM), which has been coordinating the views of several professional societies and is shortly to issue a detailed critique of the proposals.

CDC officials maintain that they are anxious to achieve a consensus on the guidelines, and plan a thorough revision in the light of the many comments that they receive. They also point out that the guidelines do not have the force of law outside public laboratories, and are intended more as a guide to local biosafety officers.

In reality, however, the CDC guidelines are likely to be widely adopted as a broad framework for dealing with potentially dangerous microorganisms, whether used in recombinant DNA experiments or not. In a letter to CDC director Dr William H. Foege, ASM asks CDC to broaden the basis for discussions with the biomedical research community — something that

Guidelines transgressor let off lightly

Washington

Dr Ian Kennedy, discovered last year to have been cloning Semliki Forest virus and not Sindbis virus, has been let off with a caution. The review committee set up by the National Institutes of Health (NIH) to investigate charges that he had infringed regulations covering recombinant DNA research in his laboratory at the University of California in San Diego has decided that no further action can be taken against him. Dr Kennedy is no longer conducting research funded by NIH and has no grant application under review for NIH funding.

The panel has also, however, recommended that, in the light of what it claims was Dr Kennedy's failure to comply with the NIH guidelines covering recombinant DNA research, during the next two years "his use of such techniques may be made subject to such additional conditions as the awarding [NIH bureau, institute or division] may require".

The NIH review committee throws little light on whether, when Dr Kennedy performed experiments using Semliki Forest virus which were at the time proscribed by the NIH rules, he did so intentionally or merely as the result of cross-infection. "It would not be fruitful for NIH staff to engage in an extensive examination of Dr Kennedy's laboratory notebooks or to interview his co-workers in order to attempt a resolution of complicated and disputed chronology."

The committee, nevertheless, faults Dr Kennedy for not seeking prior approval for recombinant DNA experiments in mouse L cells, from which transformed RNA was analysed, and says that Dr Kennedy failed to act responsibly.

Commenting on the report, Dr Donald Fredrickson, director of NIH, said that he accepted the committee's recommendations, and has asked both NIH officials and the university chancellor, Dr Richard Atkinson, to take appropriate action.

The review committee's report comes two weeks after Dr Martin Cline agreed to step down permanently as head of the division of haematology and oncology at the University of California, Los Angeles, following the university's discovery that he had used recombinant DNA molecules in treating patients with thalassaemia without the consent of the university committee responsible for protecting human subjects during clinical experimentation.

A statement issued by the university said that although both the patients and their families were told of the benefits and risks of the experimental treatment — which was carried out on one patient in Italy and another in Israel — neither university nor hospital officials were informed. The university's chancellor, Charles E. Young, added, however, that no harm had come to the patients treated by Dr Cline, whom he hoped would remain at the university.

David Dickson

CDC officials claim they would do

The question that remains is how this would affect the future of RAC. One option might be to open the committee up into a general "biosafety advisory committee", a proposal already supported by several committee members. Another would be to broaden its scope to consider some of the ethical issues raised by the use of genetic engineering techniques in medical experimentation — a direction which Dr Fredrickson is said to favour. Next month's meeting will provide some clues.

David Dickson

UK research councils

Spending too soon

Sir Geoffrey Allen, chairman of the Science Research Council, was let off lightly by the House of Commons Public Accounts Committee last week. The committee had hauled him in to explain why the council had overspent in the year 1979–80 by £4.1 million. Mr Joel Barnett, chairman of the committee, reprimanded Sir Geoffrey for errors of judgement, but seemed to accept his explanation.

The trouble began, said Sir Geoffrey, with the council underspending its budget

No Tower for Allen

by £2 million in each of the previous two years and with the promise in late 1978 from Mrs Shirley Williams, the Secretary of State for Education and Science, of an extra £33 million for the years 1979–80 to 1982–83. To make sure that unspent money would not be taken back, Sir Geoffrey decided to spend the extra allocation for 1979–80 quickly and asked universities to apply for research and equipment grants. But by July 1979 it was beginning to be apparent that the council might be overcommitting funds, especially as the new Conservative government, elected the previous April, had said that it would not honour Mrs Williams's promise in full.

By September things had got worse. The council then knew that it would only receive £5 million of the £7.5 million it had been expecting for 1979–80. An attempt to withdraw some of the extra grants awarded

was unsuccessful because equipment had already been delivered and money spent. By October, the council was forecasting excess expenditure of £7 million by the end of the financial year. In the event, it managed to save £2.9 million, mainly on international subscriptions.

The council had been caught out because equipment manufacturers were able to deliver on time and because universities, with cash flow problems of their own, submitted bills promptly. Work on the spallation neutron source at the Daresbury laboratory had also been completed earlier than expected — the council had been hoping that the bills would fall in the succeeding year.

Mr Barnett suggested that Sir Geoffrey's stratagem to ease cash flow by postponing payments amounted to deception of Parliament. But officials from the Department of Education and Science and the Treasury were more sympathetic in their evidence. The problem is that the council, like other government-funded bodies, has to plan its annual expenditure within a very small margin of error. Sir Geoffrey's request that the error be raised from less than 0.2 per cent to 1 per cent, however, was quashed by the Treasury witness who said that an announcement had been made the previous day that no easing of cost margins was to be granted for any public agency.

The council's overspending for last year is bound to make this year's financial problems even more delicate, especially with the Public Accounts Committee breathing down the council's back. In the meantime, Sir Geoffrey expects to be issued with a formal reprimand. He is unlikely to be sent to the Tower of London.

Polish academics

Degrees in question

Edward Gierek, former First Secretary of the Polish United Workers' Party, made a comeback to public life recently — fighting to defend his right to an MSc. In an interview published in the Katowice Party daily, *Trybuna Robotnicza*, Mr Gierek complained that he had been subject to a prolonged campaign of denigration.

Mr Gierek was referring to allegations made by the Krakow Party daily *Gazeta Krakowska*, that the Krakow Akademia Gorniczo-Hutnicza (Mining and Metallurgy Academy — AGH) had improperly awarded scientific degrees to prominent political figures including Zdzislaw Grudzien (former Katowice Party chief), Franciszek Szlachcic and Stanislaw Kowalczyk (former Ministers of the Interior) and to Mr Gierek himself.

Meanwhile, the Solidarity chapter at AGH had published a list of people alleged to have gained degrees improperly, claiming that in the early post-war period special crammer courses were introduced in a number of technical specialities — but

that in practice only Party and government functionaries were able to take advantage of them.

Mr Gierek says that he was only one of several thousand people who had taken advantage of the courses intended to allow people with long industrial experience to get a degree in engineering "without regular studies".

The rector of AGH is Dr Roman Ney, who last autumn became a candidate member of the Party politburo. He was swift to respond to the suggestion of irregularities, and set up a special commission to investigate the allegations. In Gierek's case it found no evidence of malpractice. AGH had on file a copy of his diploma as a mining engineer, specializing in the exploitation of coal deposits, and duly approved by the examination board. Regarding the other allegations that in 1957–61 Grudzien, Szlachcic, Kowalczyk and others had been allowed to complete four-year extramural courses in the economics of metallurgy in just over one year, the AGH department of metallurgy simply reported that these particular courses had been established on the orders of the Minister of Education.

Further queries have been raised about the academic status of Andrzej Jaroszewicz (son of the former Prime Minister). On 9 March, Krakow Technical University set up a special commission to investigate the circumstances surrounding his external degree in engineering.

These swift responses to hints of irregularity are in sharp contrast to the attitudes of officialdom which led, in 1976, to the resignation of the then President of the Polish Academy of Sciences, Professor Janusz Groszkowski, from all his public offices. Professor Groszkowski had attempted to intervene in the case of Mrs Aleksandra Hankus, who in 1964 had complained to the Krakow Technical University that a Mr Tibor Petrys had stolen her scientific results. But the Technical University refused to take any action against Mr Petrys, granted him his DSc and later helped him prepare evidence for a libel suit against Mrs Hankus.

After an 11-year struggle — during which she served an 11-month sentence for libel and was sent by the judiciary for psychiatric tests — the Supreme Court finally vindicated Mrs Hankus, stating that she had proved that Petrys had "usurped her scientific work and cheated in obtaining the degree of Doctor of Sciences". When Professor Groszkowski tried to bring a legal action against Mr Petrys, the Procurator General blocked the case for a year, since, according to Professor Groszkowski, Mr Petrys still enjoyed the support of "some organs of justice". But eventually Mr Petrys' degree was revoked.

In September 1980 Professor Groszkowski at last re-entered public life with an open letter to the academy, calling for a return to true academic standards in Polish science.

Vera Rich

US universities

Commercial interest*Washington*

Legislation passed last year by the US Congress to encourage the scientific community to take a greater interest in the commercial exploitation of their research — for example by giving universities and small businesses the right to patents resulting from federally-sponsored research — is already bearing fruit. Spurred by the new patent laws, Stanford University is considering whether to invest university funds in companies set up by faculty members to exploit their research. And the National Institutes of Health (NIH) are expected to reverse a 20-year-old policy which excludes scientists who work for profit-making companies from applying for competitive research grants.

At the same time, there are renewed pressures in Congress for legislation to offer private corporations tax incentives for supporting basic research in universities. One attraction for the universities stems from the increasing constraints on federal funding, but industrial support for university research — at present only about 3 per cent of the total — is unlikely to become a substitute for the federal government.

New NASA man*Washington*

The Reagan Administration is expected to announce shortly the appointment of Dr James Beggs, at present executive vice-president for aerospace at General Dynamics Corporation, to be the next administrator of the National Aeronautics and Space Administration (NASA). Dr Beggs was NASA's associate administrator for advanced research and technology in the late 1960's and before joining General Dynamics had acted as Under-Secretary in the Department of Energy. His name was informally mentioned by Vice-President George Bush during a visit to the Kennedy Space Centre last week, and a formal announcement about Dr Beggs' nomination is expected from the White House this week.

Meanwhile there is still no news about the post of science adviser and director of the Office of Science and Technology Policy (OSTP). A decision by the White House to include funds for OSTP in its budget request for 1982 indicates that no official decision has yet been made to eliminate the office or its activities. However, there are several rumours in Washington that the science adviser's post may be downgraded, and that OSTP could be absorbed into the Office of Management and Budget, with which it worked increasingly closely during the Carter Administration. **David Dickson**

The Stanford proposal was put to a meeting of the university's committee on research two weeks ago by Dr William Massey, professor of business administration and vice-president for business and finance. In particular, he spoke in favour of setting up a Stanford investment trust which would operate partly on capital provided by the university and partly on capital raised outside. Such a trust would make "modest" equity investments in the early financing of high-technology companies whose products derived in some way from work at Stanford.

Several scientists at the Stanford meeting, among them Dr Edward Garvin, an adjunct professor at the Stanford Linear Accelerator Center, were concerned about the potential impact on research activity of the new proposals, particularly if it meant that the potential ability to earn money for the university became a major factor in making research choices or faculty appointments.

At NIH, the change in rules covering applications for research grants is expected to be announced in the *Federal Register* within the next few weeks. It reverses a restriction applied to all funding by the Public Health Service in 1962, partly as an attempt to ensure that research funds were used to help build up university and medical schools, partly because of some well-publicized abuses.

A return to the situation of before 1962, which would not require ratification by Congress since the decision was essentially administrative, has been under discussion for several years. The document setting out the change in procedures is now said to be awaiting merely the signature of Health Secretary Mr Richard Schweiker, who is not expected to raise significant objections.

The legislation had some important administrative implications. For example, changes in the patent law now required NIH to keep track of all patents awarded to universities from federally-sponsored research, in order that the institutions should be able to exercise "march-in rights" if they consider that a patent is not being sufficiently exploited.

Dr Charles Lowe, head of the institutes' Office of Medical Applications of Research, warned that such changes could have important implications, and steps might be necessary, for example, to protect the integrity of the peer review process. His warnings were echoed by Dr Philip Siekevitz, professor of cell biology at Rockefeller University in New York, who said there was a danger that biomedical research priorities would be shifted from social need to return on investment.

Dr Donald Fredrickson, director of NIH, said he expected that many of the changes described by Dr Lowe would come about and that NIH would in particular be looking closely at the experiences of the National Science Foundation in forging ties between industry and universities.

David Dickson

UK astronomy

Change of direction

Responsibility for the construction of the La Palma observatory in the Canary Islands, Britain's hope for good optical astronomy in the Northern Hemisphere, will be handed over to Professor Alexander Boksenberg, now professor of physics at University College London, on 1 October. Professor Boksenberg will then succeed Professor F. Graham Smith as director of the Royal Greenwich Observatory, which is responsible for building and subsequently operating the La Palma site. Professor Smith, a radioastronomer, will succeed Sir Bernard Lovell as professor of radio astronomy at the University of Manchester and director of the Jodrell Bank radiotelescope.

The La Palma observatory, which will house four major telescopes, is likely to be the Greenwich observatory's largest project for a long time to come. The Science Research Council, which made the new appointment, hopes that one of Professor Boksenberg's first tasks will be to chivy the Spanish authorities, who have been responsible for some delay, into speedier action. But Professor Boksenberg sees his main task as encouraging astronomers in British universities to take the fullest possible part in the new observatory. He would like to see their involvement extend beyond the use of the telescopes for observation to the design of instruments and software, either in their own laboratories or at the Greenwich Herstmonceux site.

Since the Royal Greenwich Observatory took on the construction of the La Palma observatory, its own research effort has gradually diminished, a trend that Professor Boksenberg would like to see reversed. He hopes to encourage more astronomers to join his organization and, by collaboration with universities and Britain's other major observatory, the Royal Observatory Edinburgh, to transform the astronomy community into "a happy family".

Professor Boksenberg's previous experience seems particularly relevant to an organization involved in both instrument-building and astronomical research. His expertise in building image intensifying instruments has won him collaboration on several major worldwide telescopes. The image photon counting system, his big success, earned him observation time on the Kitt Peak and Palomar Mountain Observatories in the United States. He is at present building instruments for the faint object camera, Europe's contribution to the space telescope.

His observations have been mainly extragalactic, of quasars in particular. As well as using groundbased optical telescopes, he has also worked with data from and designed instruments for the

International Ultraviolet Explorer satellite Professor Boksenberg hopes to retain an interest in astronomy at University College London by becoming a visiting professor there **Judy Redfearn**

Oak tree wilt

Europe in dread

Brussels

The European Commission is about to launch a research programme to find a cure for the tree disease oak wilt. And a system of import controls is already in force to ensure that wood from the United States does not trigger off an epidemic as devastating as Dutch elm disease.

Experts on both sides of the Atlantic fear that if oak wilt were to reach Europe, it would in the European climate be the death knell of the oak tree. The fungus has spread slowly in the United States and is concentrated in the areas below the Great Lakes. Oak wilt is a fungus (*Ceratostoma fagacearum*) whose spores are thought to be transmitted either by the scullitus beetle or by root grafting (roots intertwining underground). The fungus clogs the tree's vessels, blocking the movement of the sap.

Controversy has surrounded the necessity for and nature of the import regime. Britain and Ireland have been in favour of tight restrictions on imported wood. But aggressive lobbying by the German furniture industry has led to relaxation for some continental industries. The German industry requires oak logs with the bark intact for veneer furniture, and the United Kingdom's Forestry Commission has stressed that the bark poses the greatest dangers of transmission.

As things are, the logs have to arrive accompanied by a certificate to show that the wood comes from uncontaminated areas of the United States. The logs can then enter the Community only through a limited number of ports and cannot then be re-exported to another member state.

Further precautions are nevertheless being taken. The Community's import regime requires that the wood is square-edged, has been dried to remove 20 per cent of the moisture and is subject to heat and air treatment. In case of doubt, the wood can also be ponded or submerged in water to kill remaining fungus. The problem for the furniture industry is that such processes do the wood no good.

The research programme is being mounted in collaboration with American and Canadian research institutes (although Canada is still unaffected). Five contracts are about to be let by the Commission to plant research institutes in the United Kingdom, Germany and Belgium. Details of the programme have not been released, but one contract will go to the Forestry Commission. The total cost of the programme is estimated at 570,000 European Units of Account (£0.54 = 1 EUA) with Europe contributing just over a half, the United States 200,000 EUA and

Canada 50,000 EUA.

Although oak wilt has been known for the past 40 years, work is still going on to map the afflicted areas. Efforts will also be devoted to gaining a greater understanding of how the disease spreads, present evidence suggests that oak wilt would spread far more quickly in Europe than in North America.

Methods exist to kill the fungus in the wood but the more important challenge is to find a way of killing the fungus in the living tree.

Problems have arisen in coordinating the timing of the research, as the Americans are in less of a hurry. European research is also handicapped by the lack of infected wood, for obvious reasons. Relations between Europe and the United States are also coloured by the knowledge that Europeans were responsible for exporting Dutch elm disease to North America in the first place.

Jasper Becker

Soviet higher education

Candidates change

The Soviet system of higher academic degrees is due for radical overhaul, according to an article in the prestigious *Literaturnaya Gazeta* last week. On the eve of the Annual General Meeting of the Academy of Sciences of the USSR, it published a major critique of the system under which the degree of Doctor of Science is now normally awarded to mature and well-known scientists approaching their fiftieth birthdays.

The author of the article, L. Orlov, is a typical product of the system. He heads a research laboratory employing 50 scientists, and has published more than 80 papers. As a senior scientific worker, holding the degree of Candidate of Science, he earns 300 rubles per month. To obtain the extra 100 rubles a month which go with the title of Doctor of Science, he is now having to rework his research results into a formal thesis, to be defended in exactly the same manner as he defended his Candidate's thesis years ago.

Orlov does not deny that the two-stage degree system had its virtues when it was originally introduced 50 years ago, when the rapid expansion of Soviet science and the lack of trained personnel meant that young scientists who had not yet completed their doctoral research were employed in posts which would normally have gone to Doctors of Science. Under such circumstances, some pre-screening of these "doctoral candidates" was necessary.

Orlov considers the double-examination system no longer relevant since Soviet science and higher education has now reached an extremely high standard. He suggests that the two-stage system is actively harmful to science. Not only do the examiners sometimes let through a young scientist whose thesis is not entirely satisfactory, "since it is, after all, only a

Candidate's thesis", but the need to produce two such pieces of original research in one academic lifetime can seriously hamper a scientist's creativity.

The current Five Year Plan, approved by the Party Congress last month, specifically calls for flexibility in research and development in order to meet the demands of the scientific and technological revolution, and for improvements in training of scientists and workers in higher education. A provocative article in a leading journal is a traditional Soviet way of introducing a possible reform to public opinion, and is usually followed by a spirited "press debate". Orlov's proposals will probably attract considerable sympathy among scientists and academics. Not only would the adoption of a single higher degree eliminate the need to write a second thesis, it would also eliminate the chagrin arising from the present system, which as Orlov notes, gives formal parity between a Soviet "Senior Scientific Worker" who at forty plus has gained his doctorate after 15 years hard work, and some "27-30-year-old young Doctor of Science from East or West Germany".

Vera Rich

Irish research and development

Marching to Georgia

Ireland is to set up a new contract research institution in the hope of persuading the 800-odd foreign companies based — tax-free — in the country to do some research and development there at last. The new institution, announced last week, and to be called the European Research Institute of Ireland (ERII), will be set up in Limerick with the help of America's Georgia Institute of Technology and will offer 50 per cent government grants to companies wishing to place contracts with it.

Ireland's Industrial Development Authority, which is responsible for the arrangements, foresees ERII as leading Ireland into its third stage of industrial development. The first was purely domestic, the second involved the establishment of foreign industry, and the third will involve research and development placing Ireland among the modern technical countries. The problems in reaching that third stage have been first, that most Irish researchers travel abroad to do their work, to America or Europe, and second, that whereas other countries offered tax incentives to companies to invest in research and development, Ireland could offer none as the firms paid no tax anyway.

The new institute is seen as the solution to these problems, with the grants substituting for tax relief, and high salaries to attract expatriate researchers back to Ireland. The Industrial Development Authority calculates that it will be paying staff at Limerick enough to match the

standard of living they might enjoy if they were based, say, at the Battelle Institute in Frankfurt.

ERII will start formally on 1 June, when two members of the Georgia Institute of Technology Engineering Experiment Station begin work in Limerick. Initially they will be housed in Ireland's National Institute for Higher Education, where president Dr Edward Walsh is said to be playing an "aggressive" part in forging links between university and industry. Recruitment is under way for eight engineers, scientists and computer specialists, but in three years' time, when ERII will move to its own buildings, it is planned that staffing levels should increase to 80.

To finance ERII, the Industrial Development Authority is paying for the buildings (£1.5 million); and the balance will come from such sponsors as Guinness Ireland, the Bank of Ireland, Allied Irish Banks and the industrial Rohan Group. Nevertheless the authority is seeking another £500,000 to launch the institute "effectively", and would like more companies to contribute to the consortium.

Robert Walgate

UK universities

Jobs to be cut?

One week after the British government's budget, the University Grants Committee has plucked up courage to make some guesses on the quantitative implications for universities. Dr Edward Parkes, the chairman, told the Public Accounts Committee of the House of Commons last week that to meet an 11 per cent cut in real terms in the universities' grant over the next three years, 3,000 academics and 4,000 other staff would have to lose their jobs. Redundancy payments to academics, said Dr Parkes, could be somewhere between £40,000 and £80,000, although realistic figures would not be known until cases had been through the courts. The total cost to the universities could be £100–200 million.

Dr Parkes has since said that in addition to 3,000 redundancies, 2,000 jobs would have to be lost through natural wastage. He estimates that 3,000 academics will leave their posts in the next three years, either through retirement or to take posts else-

where. His current plan allows for 1,000 vital posts to be refilled. A total loss of about 5,000 academic jobs represents just under 15 per cent of the academic workforce. The percentage of job losses will have to be greater than the percentage cut in the budget because economies in other areas of expenditure are virtually impossible, according to Dr Parkes.

The Association of University Teachers disagrees with that view. It is preparing a scheme to avoid large numbers of redundancies by relying on natural wastage, an early retirement option at 50 and spending one-third of the equipment grant on staff. But the scheme is unlikely to appeal to the grants committee which holds that freezing all posts would be the worst option. The problem is that those departments with the highest rate of turnover of staff — medicine, science and engineering — would suffer most, and in many cases, those are the very departments that the government would like to see least damaged. The committee prefers to maintain minimum flexibility in making new appointments and create the minimum number of redundancies.

The Science Research Council, which provides research grants to individual academics, is particularly concerned that good research should not disappear. Ever optimistic, it says that it may be able to support a few outstanding individuals who would otherwise have to go. Such support, however, is unlikely to be very significant.

The Committee of Vice-Chancellors and Principals has estimated that the grant for 1983–84 will be £80 million less than that for this year and that the loss from overseas students' fees could remove a further £70 million, a total sum short of conservative estimates of redundancy payments. The estimated costs may well have come as a surprise to the government, which is showing signs of reconsidering its plans. Sir James Hamilton, Permanent Secretary at the Department of Education and Science, told the Public Accounts Committee that his department was still attempting to work out with the University Grants Committee how the economies could be achieved. Although the budgets for 1981–82 and 1982–83 are fixed, he said, the figure quoted for 1983–84 is still only an estimate, suggesting that there may be room for further negotiation.

Universities, however, are unlikely to make up lost income by taking in more students. Contrary to the impression given in the white paper on public expenditure and by Mr Mark Carlisle, Secretary of State for Education, Sir James Hamilton told the Public Accounts Committee that the government will not increase the grant to universities that overstep their quota of students. The plan is that student numbers should remain roughly constant, implying greater competition for places as the number of eighteen-year-olds in the population continues to increase over the next few years.

Bulgarian astronomers look up and abroad

Bulgaria's new National Astronomical Observatory on Mount Rozhen, opened on 13 March 1981 by President Todor Zhivkov, was several times referred to in the inaugural speeches as a "pre-Congress gift to Bulgarian science". The term is appropriate, for the theses for the forthcoming Congress of the Bulgarian Communist Party state that in the new Five-Year Plan "primary importance should be paid to fundamental research".

This is in sharp contrast to the policies of many other East European countries, which tend to give first priority to application. According to Kiril Serafimov, head of the Bulgarian Committee for Space Research and Exploitation, "we are also a European country and understand that without fundamental science nothing is possible".

Speaking at the opening ceremony, Dr Serafimov inevitably referred to Bulgaria's "thousand-year-old" interest in astronomy — the country is this year celebrating its 1,300th anniversary of statehood. The observatory has three telescopes and a large data-processing and computer unit. The main telescope has a 200-cm hyperbolic mirror with a Coude-Richey-Cretien focusing system and will be used primarily for work on binaries and variable stars. The second, a 70-cm Schmidt instrument (effective diameter 50 cm) with a 4° x 4° field of view, will be used for preliminary search and scanning work. The smallest, a 60-cm instrument, is especially adapted for photoelectric work and brightness determinations.

The observatory is the most southerly in the socialist bloc (and, according to Bulgarian claims, the second largest optical observatory in Europe). The Rozhen team

expects to cooperate closely with the Soviet observatories, especially the Crimean Astrophysical Laboratory and the Special Astrophysical Observatory in the Caucasus, on approximately the same latitude. Intra-Comecon cooperation is well represented at Rozhen — the research programme has been worked out in collaboration with teams from the Soviet Union, the German Democratic Republic and Poland. (The optical equipment has been supplied by Carl Zeiss (Jena).) There has also been some French participation in drawing up the programme, while the data-processing equipment is largely of Western origin.

CORRESPONDENCE

Toxicity testing

SIR — The dramatic fall in Fisons' shares as a result of the withdrawal of Proxicromil emphasizes the high risks involved in drug development (*Nature* 12 March, p.81). Drug development programmes depend on animal tests for assessing long and short term toxic effects which are notoriously unreliable and expensive.

The effects of drugs on animals cannot be assumed to be the same in humans, irrespective of whether results indicate that a drug is "safe" or "harmful". Legislators should accept this fact and release toxicologists from the present "check-list" testing system which has replaced scientific initiative with standard tests of dubious relevance which are carried out on ever increasing numbers of animals.

On scientific, economic and humanitarian grounds current toxicity testing protocols should be refined to ensure the most efficient use of animals and to incorporate valid non-animal screening tests wherever possible.

Inherited tolerance?

SIR — I would like to suggest a more straightforward explanation of the fascinating findings of Gorczynski and Steele¹ than the one they have opted for. There is a strong possibility that mouse semen contains some cells other than sperm — lymphocytes, for example. In the mouse, semen is ejaculated intra-cervically, rather than intra-vaginally as in humans. Thus any non-sperm cells will be directly introduced into the uterus in the mouse. Not much is known about the fate of such cells although it appears that sperm are rapidly removed by phagocytosis. The pregnant uterus, however, is to some extent tolerant of foreign cells. Short and Yoshinaga², Wilson³ and Lions⁴ have described experiments which show that heterologous tumour cells can persist for several days in the rat uterus and that these can enter the mucosa only at the time of implantation in pregnancy. Thus the endometrium becomes receptive to foreign cells at the time of implantation, and so non-sperm cells present in semen could presumably become established in the endometrium and might then enter the embryo after implantation.

If we then suppose that tolerance involves clones of cells in a manner analogous to immunity and that some of the non-sperm cells are competent for the transmission of the tolerant state, the embryo might be rendered tolerant to the same antigens as the father. Moreover, if the chances of such an invasion of the embryo were less than 100 per cent, tolerance of a particular antigen would be found in only a proportion of the embryos and some would be tolerant to both of two antigens whilst others would be tolerant only to one. Since the postulated cells conferring tolerance are differentiated they would play no part in embryogenesis but would be carried and perhaps multiplied in the embryo. In subsequent generations, the chances of transmission of the cells would be finite and

the incidence of tolerance to specific antigens would decline. In the mothers, the return to the non-pregnant state after parturition would, presumably, involve the rejection of any foreign clones of cells in her tissues. Thus, subsequent matings to non-"tolerized" fathers would not result in the transmission of previous tolerant states.

In this way, the essential aspects of the Gorczynski and Steele experiments might be explained along rather less controversial lines than at present. At the very least, the possibilities raised here must be eliminated before we venture to compromise the doctrine of Weismann and begin resurrecting the long dead Lamarck.

Exhibit dismay

SIR — I have been following with great interest and some dismay the extended correspondence in *Nature* about the nature and significance of new exhibits in the British Museum (Natural History). I wish to comment on recent letters from three colleagues and fellow-countrymen of mine^{1–3}, one British colleague⁴ and one French colleague⁵.

McKenna¹ and Nelson² speak out against Halstead and in favour of cladistic or Hennigian systematics, to which a considerable part of the new dinosaur exhibit is devoted. Both McKenna and Nelson are now at the American Museum of Natural History, with which I was associated for many years. They belong to a small group now there which is representative neither of the staff of the museum as a whole nor of the majority of American palaeontologists, who, like me, reject Hennigian procedures.

Gould³ is at the Museum of Comparative Zoology, with which I was also associated for some time. He proclaims that he is not a cladist and "did not care for" the cladistic exhibits at Cromwell Road. He also claims that his theory of punctuated equilibrium is not a Marxist plot and notes that the co-author of the theory, Eldredge, is not a Marxist. I do not wish to discuss Marxism in this connection, but I do note that the punctuated equilibrium of Eldredge and Gould is only one facet, taken to an extreme, long since incorporated in the synthetic or if you like, neo-Darwinian, theory of evolution.

Howgate⁴ named me as being "by no means averse to the idea of leaps," that is, to saltatory evolution. He quotes as evidence a statement by me in a book published in 1949 (not 1976 as he has it) that rates of evolution in the horse family varied considerably. I did not state or imply that the rates were ever saltatory, that is, instantaneous.

Janvier⁵, of the Laboratoire de Paléontologie des Vertébrés of the University of Paris claims that cladism is "directly descended from Darwin's ideas on phylogeny and systematics." In context this implies that Darwin was a saltationist, which is not true.

He also notes that some French scientists (Grassé as an example) are anti-Darwinian. In fact French biologists, with the exception of a few radicals, have always been anti-Darwinian, at times for no clear reason other than chauvinism.

Evolving theory

SIR — The letter from H.W. Ball and 21 colleagues (*Nature* 12 March, p.82) contains the following astounding statement: "But the theory of evolution would be abandoned tomorrow if a better theory appeared".

The lapse of time between the appearance of a "better theory" and the abandonment of its predecessor can be established with fair accuracy in many topics of science. The history of science provides a large number of such events. Accordingly, the lapse of time between the appearance of the new and the relinquishing of the old might be regarded as one of the many facts of science. Your 22 correspondents, apparently seriously, estimate the magnitude of this lapse of time as one day. One day! They declare their devotion to fact and their abhorrence of prejudice. Are their other facts of a similar colour I wonder, or does evolution evolve more rapidly than any other field of science?

R.V. HESKETH

*Berkeley Nuclear Laboratories,
Berkeley, Glos., UK*

SIR — Bertolt Brecht put these words into the mouth of Galileo¹:

"And what we discover today we shall wipe off the slate tomorrow and only write it up again once we have again discovered it. And whatever we wish to find we shall regard, once found, with particular mistrust. So we shall approach the observation of the sun with an irrevocable determination to establish that the earth does *not* move. Only when we have failed, have been utterly and hopelessly beaten and are licking our wounds in the profoundest depression, shall we start to ask if we weren't right after all, and the earth does go round."

As far as evolution is concerned, I think most biologists would agree that "the earth does go round", there being no better way of accounting for the facts *at present*. So how are we to understand the over-cautious round robin from the British Museum? There is a world of difference between "If the theory of evolution is correct . . .", and ". . . evolution is a fact, proven to the limits of scientific rigour." Most of us, like yourself, would wish to be more positive than the first but less dogmatic than the second. In these days of proliferating crazies, the British Museum should not risk giving them more ammunition.

NEWS AND VIEWS

Genes pieced together — exons delineate homologous structures of diverged lysozymes

from Peter J. Artymiuk, Colin C.F. Blake and Albrecht E. Sippel

GILBERT¹ has proposed that the arrangement of eukaryotic genes in a mosaic of introns and exons might facilitate the evolution of new proteins. He suggests, for example, that if exons correspond to functions, recombinations within introns could put together new proteins with new combinations of functions. Blake² has pointed out that if exons also correspond to folded protein structures the new protein is more likely to achieve structural stability by being a combination of folded sub-structures.

If these ideas are correct, we would expect to discover in different proteins folded units of common structure and function, derived from common exons, combined with units of different structure and function. Examples may already be to hand in the dehydrogenases³, and in triose phosphate isomerase, pyruvate kinase⁴ and KDPG-aldolase⁵, but in the absence of the details of their exon/intron patterns this cannot be confirmed. The definition of four exonic regions in the hen lysozyme molecule⁶ allows a comparison of these regions with the regions of structural and functional homology in T4 phage lysozyme^{7,8,10}. This comparison is, intriguingly, consistent with the hypotheses of Blake and Gilbert, although as an isolated first attempt it cannot be adduced as proof.

Determination⁹ of the structure of T4 phage lysozyme did not at first suggest that there was a close resemblance to hen egg-white lysozyme. Rossmann and Argos⁷ later showed that substantial portions of

the molecules were structurally similar. A number of small deletions in one molecule (or insertions in the other) made residues 1–73 of T4 lysozyme overlap with residues 25–101 of hen egg-white lysozyme. Two large insertions in the T4 chain brought out homologies in residues 100–105 and 150–163 of T4 with residues 104–109 and 113–126 of hen. The structural equivalence is shown schematically in the figure. In all, 78 α -carbons were shown to be equivalent with a r.m.s. difference of 4.1 Å. Using somewhat different techniques that do not allow insertions or deletions in the chains, Remington and Matthews⁸ confirmed the similarity and showed that residues 27–109 could be made to overlap with residues 1–80 of T4 lysozyme with a r.m.s. α -carbon difference of 6.0 Å. It is important to note that the structurally equivalent regions correspond to, at most, two-thirds of the hen lysozyme molecule and less than half the T4 lysozyme molecule, and for each lysozyme large contiguous regions of chain have no equivalent in the other molecule.

Rossmann and Argos⁷ noted that the equivalent regions encompass the active site regions of each of the molecules and showed that the binding sites for an *N*-acetylglucosamine monomer were only 0.8 Å apart in the two enzymes. Recently Matthews and his colleagues (see this issue of *Nature* p.334) have extended this

positional similarity to a bound tri-*N*-acetylglucosamine moiety, and to Glu 11 and Asp 20 of T4 lysozyme with the catalytic Glu 35 and Asp 52 of hen lysozyme¹¹. Furthermore, they suggest that sugar C is bound in a similar mode in the two enzymes and that sugar D is distorted in T4 lysozyme by a close approach of its 6-hydroxyl to protein groups similarly positioned with respect to the binding groups of sugar C, as in hen lysozyme¹¹. These observations imply that the structural similarity is accompanied by a similarity in substrate binding and catalytic mechanism. Although each separate piece of evidence is circumstantial, their combination argues strongly for an evolutionary relationship, or more unlikely, an extreme case of convergence in structure and function between the two lysozymes.

Sippel and his colleagues⁶ have recently determined the exon pattern in the hen lysozyme gene. They have found that the gene contains four exons, corresponding to residues –18 to 28 (the signal peptide of prelysozyme and residues 1–28 of mature lysozyme), 28–81/82, 81/82–108 and 108–129. They note that although the exon pattern is related to some degree to the structural division of the hen lysozyme molecule, its relation to the functional units of the enzyme is better established. For example, exon 2, which codes for residues 28–81/82, includes the catalytic residues and a cluster of amino acids that bind sugars C, D, E and F of the oligosaccharide substrate and could

A schematic diagram showing the relation between hen egg lysozyme and T4 phage lysozyme. The solid bars in the centre show the residues which are considered equivalent by Rossmann and Argos⁷. The rectangles marked a and a' define the 80-residue segments aligned by Remington and Matthews⁸. The lower rectangles and arrows mark the exonic transcript regions defined by Jung *et al.*⁶.

perhaps function as a primitive glycosidase. Exon 3, which codes for residues 81/82–108, corresponds to a protein fragment that, combined with the exon 2 product, could give additional substrate specificity, determine the cleavage frame for the alternating NAG–NAM chain and increase the catalytic efficiency of the active centre. Exons 1 and 4, on the other hand, code for protein fragments that are not directly involved in the catalytic function, but may increase the stability of the hen lysozyme molecule and/or carry some as yet unknown biological functions of the enzyme.

The regions of structural homology in T4 and hen lysozyme described by Rossmann⁷ and Matthews⁸ can now be compared with the exon pattern of hen lysozyme defined by Sippel⁶ (see the figure). First, it is clear that residues 1 to 24 or 26 (depending on the comparison) of hen lysozyme, corresponding closely to exon 1 (residues 1–28), have no counterpart in the T4 lysozyme molecule; that is, in T4 lysozyme exon 1 is absent. Second, the principal region of overlap between the two lysozymes corresponds closely to the combination of exons 2 and 3 (residues 28–108). In Rossmann's analysis this region corresponds to residues 25–101 of hen lysozyme and residues 1–73 of T4 lysozyme, while Matthews' analysis⁸ slightly extends and alters the overlap to include residues 27–109 of hen lysozyme and residues 1–80 of T4 lysozyme. Rossmann's analysis⁷ also lines up residues 104–109 of hen lysozyme with residues 100–105 of T4 lysozyme, but this requires a 25-residue insert in the T4 sequence to incorporate it in the major overlap. Accepting some ambiguity with regard to residues 102–109 of hen lysozyme, the correspondence to the combination of exons 2 and 3 is close. If Rossmann's analysis⁷ is restricted to these two exons, the overlap reduces the r.m.s. α -carbon difference from 4.1 Å to 3.2 Å. Finally, correspondence to exon 4 (residues 108–129) of hen lysozyme seems less clear-cut than for exons 1–3. Matthews⁸ does not match it with any part of the T4 lysozyme. Rossmann and Argos⁷ overlap residues 113–126 of hen lysozyme with residues 150–163 of T4 lysozyme but with a rather high r.m.s. α -carbon difference of 6.2 Å. In these circumstances it is difficult to tell whether there is or is not a region of

the T4 lysozyme molecule that corresponds to exon 4 of hen lysozyme.

In conclusion, with the exception of exon 4, the agreement between the exons of hen lysozyme and the structural homology with T4 lysozyme is very close. Exon 1 is absent from the T4 molecule and the principal region of overlap corresponds to exons 2 and 3. In view of Sippel's conclusion⁶ that exon 2 could represent a primitive glycosidase minigene on which substrate specificity was conferred by the product of exon 3, it is tempting to see exons 2 and 3 as the functional nucleus of the lysozyme molecule. The presence of these two regions in T4 lysozyme could account for the similarity in substrate binding and catalytic mechanism suggested by Matthews¹⁰. In addition, the absence of exon 1, and the possible absence of exon 4, are not unreasonable if, as Sippel suggests, they play a role in the stability, rather than catalytic function, of the hen lysozyme molecule. Their stabilizing influence may be taken over in the T4 lysozyme molecule

by the large C-terminal lobe or domain, which has no equivalent in the hen molecule. Indeed, Matthews¹⁰ suggests that this C-terminal region of T4 lysozyme has a function in binding the cross-linked peptide of *E. coli* cell walls, which is not necessary for hen lysozyme.

Although this analysis must be regarded as provisional until other proteins can be examined from a similar point of view, this comparison of T4 and hen lysozyme is fully consistent with the view that recombination within introns can rearrange functional exonic regions into new patterns in new protein products. What is most encouraging is the promise that protein structural analysis can help us identify and predict exons in genes and trace evolutionary events at the level of DNA, and conversely that sequence analysis of gene DNA can help us to understand the structure, function and evolution of the final protein product. □

We are grateful to Professor B. W. Matthews for letting us see his manuscript before publication.

Waves, turbulence, solar convection and ozone

from Michael McIntyre

THE Earth's atmosphere and oceans are increasingly being used as an outdoor laboratory, not only providing information about the behaviour of our environment but also insight into certain difficult, unsolved problems in fluid dynamics. These involve wave-like and turbulent fluid motions at huge Reynolds numbers which are inaccessible to both indoor laboratory experiment and simulation on the world's largest computers.

Empirical information is specially important for the ill understood problem of turbulent motion, and one paper given at a recent conference* was of unusual interest in this respect. J.J. Finnigan (CSIRO, Canberra) and F. Einaudi (Georgia Institute of Technology, Atlanta) have produced what may be the first really detailed information about how an internal gravity wave interacts with pre-existing turbulence. In the case they analysed the wave was nearly monochromatic, and by good fortune had propagated past the 300 m tower and ground-level microbarograph array at the Boulder Atmospheric Observatory, Colorado at a time when a large volume of data was being taken. Turbulent and wave-induced fluctuations could be separated cleanly, revealing how

the turbulent Reynolds stresses varied with the wave motion. To a first approximation the turbulence behaved quasi-elastically, indicating that rapid-distortion turbulence theory should apply. The observed behaviour is quite different from what would have been expected from 'eddy viscosity' or 'mixing length' ideas. It is encouraging to see further direct evidence for the use of rapid-distortion theory, which is complete and rational within its limits of applicability. Other recent lines of evidence come from the work of J.C.R. Hunt and his collaborators at Cambridge on turbulent flow over hills and around buildings, for which rapid-distortion theory is proving to be more useful than previously supposed, and from an estimate by D.O. Gough (Institute of Astronomy, University of Cambridge) using recent observations of the solar 'five-minute' oscillations, showing clearly that they must interact with the Sun's turbulent convection zone in a similar way.

As suggested some years ago by A.A. Townsend, the same ideas seem likely to be important also for understanding the generation of ocean waves by wind. Other aspects of that celebrated and still unsolved problem were illuminated by E. Mollo-Christensen (MIT) and A. Ramamonjia-

Michael McIntyre is in the Department of Applied Mathematics and Theoretical Physics at the University of Cambridge.

risoa (University of Aix-Marseille), who presented new laboratory evidence of strongly nonlinear coupling between the air flow and modulational instabilities of the waves. More light was thrown on the instabilities themselves by a remarkable series of photographs and measurements by Y.-M. Su and A.W. Green (NORDA, NSTL Station, Mississippi) showing a succession of instabilities in a train of moderately steep, monochromatic waves. The waves were generated by a wavemaker about 16m long in an outdoor basin 100 × 340m. A small-scale, essentially three-dimensional instability, very regular in form but as yet unexplained theoretically, was prominent. Its nonlinear evolution appeared to culminate in scattering of some of the wave energy in a direction about 30° away from that of the primary wavetrain, a phenomenon hardly likely to have been identified in a narrow laboratory tank.

Most of our knowledge about the large-scale, low-frequency oscillations known as Rossby waves comes from observations of the atmosphere and ocean, where in practice the waves often have large amplitudes and occupy the no-man's land between 'waves' and 'turbulence'. Experimental possibilities are severely restricted not only by small dimensions but also by the constancy of gravity in the laboratory. Rossby waves can be expected to occur also in the stably stratified interiors of rotating stars. Y. Q. Kang and L. Magaard (University of Hawaii) produced what appeared to be the clearest example yet observed of mid-latitude, oceanic Rossby waves, in a 'baroclinic' mode unobtainable in the laboratory. The wavelength was about 300 km and the waves had a phase velocity towards the north-west and group velocity towards the south-west with magnitudes of the order of a centimetre per second. A point of special interest was that the waves had extremely large amplitudes, as measured by the ratio of a typical particle velocity to a typical phase velocity — well in excess of the kind of amplitudes at which most waves in fluids become very strongly dissipative.

Rossby waves in the atmosphere, too, were a topic of renewed interest. A number of papers were on theoretical models related to the recent work of J.G. Charney (MIT) and his collaborators, in which global-scale, topographically generated Rossby waves are allowed to interact with an azimuthal mean flow driven by a constant forcing. This simple interaction seems capable of explaining the observed tendency of the atmospheric circulation to flip between quasi-stable states, with large and small amplitudes in those wave components which are phase locked to the topography. The large-amplitude states are associated with 'blocking' patterns and persistent spells of anomalous weather. In winter the same Rossby waves can penetrate the stratosphere, where under the right conditions they trigger 'sudden

warmings' — sporadic but spectacular upheavals in the state of the polar stratosphere in which dynamically induced subsidence of air over the polar cap causes large, adiabatic temperature rises. Whether or not a sudden warming occurs is sensitively dependent on conditions in the stratosphere itself, as well as in the troposphere. At the concurrent meeting on the 'Upper Atmosphere' there were signs that our understanding of the conditions favouring sudden warmings may be about to improve significantly. Recent progress in the dynamical theory, together with the uniform global coverage offered by infrared satellite observations, have led to better ways of analysing the observations

and more illuminating comparisons with computer simulations. Some real clues are emerging as to how and why the behaviour of the stratosphere differs from that of the computer simulations, and we can await the results of current modelling efforts with considerable interest. The sudden warming is a large-scale dynamical experiment which nature kindly performs from time to time. It is one of the crucial tests of our ability to simulate the large-scale dynamics of the stratosphere. The dynamics, in turn, are one of the necessary ingredients in attempts to understand the stratospheric circulation in general, and to predict the effects of pollution on the ozone layer in particular. □

Climatic variation in San Diego

from M.J. Salinger and C.B. Sear

DURING anomalously warm and dry weather in San Diego in January, climatologists met to discuss climatic variations. Much of the meeting* centred on the implications for global climate of the likely increase in atmospheric CO₂ concentration during the next few decades, but other topics, including recent climatic change and palaeoclimatic studies, were also discussed and will be highlighted here.

A new Southern Hemisphere data set, covering 1972 to 1979, has recently become available from the Australian Bureau of Meteorology and several aspects of the circulation down under were discussed, using these data. M.L. Blackmon and T.J. Phillips (National Center for Atmospheric Research (NCAR), Boulder, Colorado) examined the 1,000 mbar height data and showed that, between 1972 and 1979, there was a band of high variance between 40° and 60°S from south of Africa to New Zealand. Together with the results of K.E. Trenberth¹ which show a similar band of maximum variance in mid-tropospheric data at 500 mbar, these investigations suggest that the circulation of the Southern Hemisphere consists essentially of one major storm track. Corroborative evidence also came from J.C. Rogers (Ohio State University) who used Eigenvector analyses to show that negative correlations exist between high and middle latitudes in the same longitudinal band during the Southern Hemisphere summer. These results suggest that, when the westerlies in one sector of the hemisphere are strong, they are also strong in other sectors.

Chiu and Newell (MIT) described similar analyses for the Northern Hemisphere using upper air data for the period 1959–79 and concluded that the non-seasonal low-level changes during this period were dominated by the 'Greenland see-saw'

which has been described previously, notably by H. van Loon and J. Williams². The see-saw operates when surface variables, pressure and temperature, in the region of southern Greenland and northern Scandinavia are negatively correlated. At higher levels (200 mbar) Chiu and Newell found that a persistent pattern, centred over Greenland, dominated. They suggested that this could be related to the Southern Oscillation which is a quasi-periodic four to six-year climate oscillation centred over the Pacific and linked to such important phenomena as El Niño.

First described as early as 1936 by Walker and Bliss, the Southern Oscillation is receiving a lot of attention because it is one of the best defined quasi-regular climatic events. Although primarily a tropical Pacific phenomenon, it has often been proposed as an important controlling mechanism for variations over much of the globe. Indeed, the studies described in San Diego confirmed old and elucidated new 'teleconnections' between the tropical Pacific and higher latitudes in both hemispheres. K.E. Trenberth and D.A. Paolino (University of Illinois) reported the variability of the Northern Hemisphere surface circulation showing connections with the Southern Oscillation. They used data from the period 1925–77 and Empirical Orthogonal Function (EOF) analyses to show that the dominant pattern in all seasons was one associated with anomalies centred on the Aleutian and Icelandic low-pressure areas. The time series of this pattern have significant periodicities at about six years which, they speculate, are associated with the Southern Oscillation.

Of the researchers who discussed synoptic analyses, only D.J. Shea (NCAR)

M.J. Salinger and C.B. Sear are at the Climatic Research Unit, University of East Anglia.

*The first AMS conference on 'Climate Variations'. See footnote on previous page.

presented results from global data using EOF analyses. His sensitivity studies suggested that the first three EOFs of temperature were stable but that none of the EOFs of precipitation is so, implying a very high degree of randomness in spatial patterns of precipitation. This is an important consideration, particularly for those who are searching for a CO₂-induced climatic change and are finding analogues from within the recent period.

Seemingly far removed from such studies were those using palaeoclimatic data to investigate long-term climatic change. Studies of deep-sea cores have provided considerable insight into climatic variations on such time scales. W.C. Prell (Brown University) concluded from examination of foraminifera assemblages from the western Arabian Sea that a distinctive assemblage occurs when the summer monsoon causes intense upwelling. The sediments provide a record of monsoonal upwelling variations over the past 150 thousand years which suggests that the monsoon was more intense from about 8,000 to 10,000 years ago — a time of increased precipitation in Africa and Arabia³. The more intense monsoon coincides with the dates of maximum Holocene warming reported in Australia and New Zealand. There is now mounting evidence that the most pluvial and warmest periods of the past 15,000 years did not occur simultaneously throughout the globe and this should be borne in mind by those attempting to produce analogues for a warmer, high-CO₂ world using data from the Holocene.

A model of oceanic moisture feedback to ice sheets in the Northern Hemisphere was advanced by W.L. Ruddiman and A. McIntyre (Lamont-Doherty Geological Observatory, Columbia University; see ref. 4). They have found evidence from a core in the central North Atlantic that, for the past 250 thousand years, North Atlantic moisture feedback has amplified Milankovitch forcing, defined in summer insolation, from the 23,000-year precessional cycle, and have postulated a feedback mechanism in which orbitally controlled changes in summer insolation over the North American ice regulate meltwater/iceberg outflow to the North Atlantic. The feedback is such that when summer insolation is high, ice rafting into the ocean causes the formation of a low-salinity layer at the surface. This in turn restricts moisture transport to the ice sheet. The opposite happens when insolation is low. Accelerated shrinkage or growth

occur accordingly and positive feedback results.

Among the many modelling studies discussed were some concerned with palaeoclimatic circulation. A low-order general circulation model (GCM) of the Earth's atmosphere, developed by B.L. Otto-Blieser (University of Wisconsin-Madison), was used by J.E. Kutzbach (at the same institution) and T. Webb III (Brown University) to simulate the climate 18,000 years ago. The rationale behind the use of a low-resolution model was that palaeoclimatic data have similar resolution. If the model is successful, then both modern data and data from 18,000 BP can be used to simulate climate in the intervening epochs. Their simulation of the climate of 18,000 BP had an enhanced westerly gradient across the US with the strongest flow just south of the ice sheet, in agreement with earlier GCM results⁵.

S.L. Thompson, E.J. Barron and S.H. Schneider (NCAR) reported energy balance modelling studies, based on the work of Barron *et al.*⁶, which investigated the causes of the ice-free mid-Cretaceous climate. Their results suggest that changes in zonal palaeogeography (continental drift) are an important forcing mechanism for climate change but that meridional temperature distribution cannot be simulated successfully without additional feedback assumptions. Their model included albedo and cloud feedbacks and meridional heat transport changes but could still not model the Cretaceous temperature distribution. Thompson and his colleagues speculated that to attain Cretaceous levels of warming, the Earth could require additional external forcing from the Sun. Although indirect, this is one of the first quantitative investigations implicating solar constant changes as causes of climatic change on the time scale of hundreds of millions of years.

Few new results were presented on the recurrent theme of carbon dioxide, but modellers of a CO₂-warmer Earth did not get away from San Diego without warnings, notably from S.H. Schneider and S.L. Thompson that a CO₂-warmer Earth has so far been modelled using an instantaneous increase in CO₂ concentration, whereas, of course, in the real world the concentration increase occurs very slowly⁷. Thompson and Schneider suggest that the thermal inertia of the upper ocean, together with vertical mixing of the deep ocean waters, could delay the response of the globally averaged surface temperature to increasing CO₂ by a decade or so relative to equilibrium calculations. They suggest further that the evolution of surface climate anomalies, as CO₂ increases, may be significantly different from that suggested by equilibrium modelling results. They stress that the nature of this transient response is a major uncertainty in present CO₂-climate change studies and that further research into this topic is urgently required. □

The return of Halley

from David W. Hughes

HALLEY'S comet was last seen at the end of May 1911 when it was at about Jupiter's distance from the Sun and heading out into the Solar System beyond the orbit of Neptune. Aphelion was reached in 1948. The comet has been on its way back ever since.

The search for Comet Halley began, rather optimistically, in November 1977 when observers at two of the United States' largest telescopes unsuccessfully attempted to recover it more than eight years before the predicted perihelion passage date of 9 February 1986. The comet's estimated magnitude was fainter than 26 at that time.

The early recovery of the comet is of considerable importance as this would enable a valuable check to be made on the predicted orbital parameters. Comets are much affected by the gravitational perturbations induced by the major planets. In the case of Halley this causes a slow variation in the period, between extreme values of about 76.1 yr and 79.4 yr, and a continuous increase in the longitude of the nodes. Spacecraft missions, like the planned Giotto Comet Halley flyby, require an accurate knowledge of the comet orbit to enable the spacecraft to fly as close to the comet as possible. At the last apparition the comet was recovered by Max Wolf using a 1 hour photographic exposure with the 72 cm Heidelberg reflecting telescope. The comet appeared as a small fuzzy image of magnitude 16. It was 3.4 AU from the Sun, in the outer regions of the Asteroid belt and 7.5 months from perihelion passage. At the present time the comet is 14 AU from the Sun and has an estimated magnitude of 24.7. (A change of 1 in magnitude is equivalent to a brightness ratio of about 2.5, so a comet of magnitude 16 is 3,000 times brighter than a comet of magnitude 24.7.)

The estimated path of Comet Halley is shown in the accompanying figure. Data for this figure have been extracted from *The Comet Halley Handbook: an Observer's Guide* which has been produced for the International Halley Watch by Donald K. Yeomans of the Jet Propulsion Laboratory, Pasadena, California (JPL publication 400-91 1/81). The comet is near the boundary of the constellations Canis Minor and Monoceros. The fact that the Milky Way acts as a backdrop obviously makes the search more difficult. The loopy path of the comet against the sky background is caused mainly by the movement of the observer. The comet is

The predicted path of Halley's comet for the next two years. The comet is mainly in the constellations Canis Minor and Monoceros. a, b, c, d, e and f represent its positions during January 1981, April 1981, October 1981, April 1982, October 1982 and April 1983 respectively. In January 1981 the comet had an estimated nuclear magnitude of +24.8 and this brightens steadily to about +22.5 in April 1983.

seen at maximum right ascension in October and at minimum right ascension in April. In this time interval the Earth has moved about 300,000,000 km, from one side of its orbit to the other. As the comet approaches the Sun the size of the loop increases. The most favourable time of the year for recovery will be when it has its maximum rate of angular movement against the sky background and can thus be more easily distinguished from a star. This occurs during the horizontal portions of the curve in the figure, at times roughly corresponding to winter and summer.

The fame of Halley's comet is not due to its brightness. Indeed, many of the accounts we hear from parents and grandparents of the appearance of the comet in 1910 do not refer to Halley at all but to the Daylight Comet, 1910 I, also known as the Great January Comet. Unfortunately, the forthcoming apparition will be unfavourable. Many of the waiting public will be disappointed as the comet will not be obvious to the naked eye. When Halley is at its most active it will be on the opposite side of the Sun to Earth and its maximum magnitude will be only about 2.9, about 2.5 times fainter than Polaris, the pole star.

Yeomans reviews the observing prospects and provides a series of charts showing the elevation, azimuth and magnitude of the comet in the morning and evening sky for latitudes 40°N, 30°N, 20°N, 20°S and 30°S. Two things are only too clear. Southern Hemisphere observers are better placed than Northern Hemisphere ones and people living at latitudes above 50°N are going to have considerable problems. It will be worth the effort though. One thing is certain, the similarity between our 'three score years and ten' and Halley's orbital period makes this a once in a lifetime experience for the large majority of us. □

Hybrid myosins

from Dixie W. Frederiksen

A recent paper by Sellers, Chantler, and Szent-Gyorgyi¹ of Brandeis University has provided important new insight into the control of contraction in molluscan muscle and into the properties of myosins from a wide variety of species and cell types. It is the interaction of actin with myosin that brings about activation of the myosin Mg-ATPase and the production of mechanical work for contraction or cell motility². The intracellular concentration of free calcium controls this interaction by mechanisms which differ in different systems.

In vertebrate striated muscle the primary effect of calcium is on troponin, a protein bound to actin and to tropomyosin on the thin filament of the sarcomere³. Conformational changes induced by calcium lead to a removal of inhibition of the actin-myosin interaction. In the striated muscles of molluscs and some other invertebrates, calcium acts directly on myosin in the thick filament to induce conformational changes that allow myosin to bind to actin⁴. In smooth muscle the situation is less well understood but the primary action of calcium appears to be an activation of a myosin light chain kinase. This produces a phosphomyosin which, unlike the unphosphorylated protein, can be activated by actin⁵. Additional effects of calcium have been reported for vas deferens and vascular smooth muscle⁶ and it has also been shown that smooth muscle contraction may be calcium regulated through an actin-linked system⁷.

In all muscle and in most non-muscle cells, the myosin molecules⁸ are hexameric species that consist of two 'heavy' (200,000 molecular weight) and four 'light' (14,000–31,000 molecular weight) polypeptide chains. There are two classes of light chains; the two 'non-essential', or 'regulatory', light chains are relatively easily removed from the major portion of myosin without loss of biological activity while the two 'essential' or 'alkali' light chains are removed from myosin only after rather harsh treatment with alkali or denaturant and their loss is accompanied by loss of ATPase activity. The intact myosin molecule is highly asymmetric with helical portions of the heavy chains contributing most to the length of the molecule. The light chains and globular portions of the heavy chains comprise a pair of structures at one end of the molecule that each contain an actin-binding and an ATPase site.

The detailed structures and functions of the myosin subunits vary from one cell type to another and, in their recent paper, Szent-Gyorgyi and his colleagues illustrate some important similarities and distinc-

tions among the various regulatory light chains from different myosins. Using some of the techniques they developed earlier⁹, they prepared approximately twenty different hybrid myosins containing the heavy and alkali light chains of scallop adductor myosin and two regulatory light chains from other myosins. They then tested regulatory light chains from vertebrate and invertebrate striated muscle, gizzard smooth muscle and platelets. Since all of these foreign subunits bind easily to light chain-depleted scallop myosin, the heavy chain-binding sites on all the regulatory light chains must be similar, as had been previously suggested by Weeds and his collaborators¹⁰.

The properties of the hybrid myosins are consistent with the idea that smooth muscle, as well as molluscan and some other invertebrate striated muscle myosins, are calcium-sensitive regulatory switches for the contractile process, but the vertebrate striated muscle has no myosin switch. Not surprisingly, the regulatory light chains from scallop and other molluscs restore full calcium ion sensitivity to the scallop myosin. In addition, light chains from crab, cricket, gizzard and platelets also form hybrids that bind calcium and require the divalent cation for actin activation of the ATPase. (The concentration of free calcium necessary for activation of these hybrids is higher than that required for the molluscan hybrids.) Vertebrate and lobster striated muscle myosin light chains produce calcium-insensitive hybrids without high-affinity calcium binding sites. Phosphorylation of the vertebrate striated and smooth muscle light chains (see *Myosin phosphorylation* *Nature* 287, 191; 1980) did not affect the enzymatic properties of the hybrid myosins.

The Szent-Gyorgyi group has also resolved some of the puzzling questions about the mechanism of calcium control in molluscan muscle. Because the first regulatory light chain is much more easily removed from scallop myosin than the second, it seemed possible that the two light chain binding sites on scallop myosin are not identical. In an elegant series of experiments using labelled regulatory light chains, they showed that the light chains are removed in an order independent of the order of combination. The subunits bind to the main portion of myosin in a cooperative manner. The cooperativity is negative,

however, since the affinity of myosin for light chain drops dramatically after the first one is bound. The affinity of light chain-depleted scallop myosin for foreign light chains is as great or greater than the

affinity for scallop light chains. Although this may be a fortuitous property of scallop myosin, it is intriguing to ask what might be learned using other light chain-depleted myosins in similar experiments. □

Two distinct types of oceanic plateau

from Peter J. Smith

THE many refraction studies carried out over the oceans during the past twenty years have shown the basic structure of the oceanic crust to be remarkably uniform. The three-layer model proposed by Raitt (in *The Sea*, Wiley, 1963) in pre-plate tectonic, and almost pre-ocean floor spreading, days still generally holds good, notwithstanding the discovery of systematic variations in some lithospheric properties with age. At the same time, however, the ocean basins contain some obvious anomalous features, of which active ridges are the most conspicuous and hot spots the most controversial. And then there are the 'ocean plateaus' — broad aseismic platforms standing high above the ocean floor and usually topped with thick deposits of calcareous sediments.

Some of these plateaus (Rockall Bank and Seychelles Plateau, for example) have long been regarded as continental fragments, presumably broken off from larger landmasses during continental redistri-

bution. But others (for example, Broken Ridge and Shatsky Rise) are thought to be truly oceanic, although the processes by which they are formed are unknown. To test this two-fold classification and put it onto a more systematic basis, Carlson *et al.* (*Earth planet. Sci. Letts* **51**, 171; 1980) have now collated the seismic refraction data from 11 of the many oceanic plateaus known, showing that the two types are structurally distinct as might well be inferred from their supposedly different origins.

Of the 11 features studied, three were already known to be underlain by rock of continental type. Thus Rockall contains Lower Eocene granites; granitic rocks are exposed on the Seychelles Plateau; and gneissic rocks have been recovered from the basement of the Falkland Plateau by the Deep Sea Drilling Project. In addition,

Saya de Malha Bank is apparently part of the same physiographical feature as the Seychelles, the Mozambique Plateau is close to Africa and thought to be a piece broken from it, and Lord Howe Rise is likewise thought to be a fragment from nearby Australia, although in these three cases there is apparently no direct evidence of the presence of continental material.

But direct evidence or not, the seismic velocity-depth profiles suggest that these six platforms are of similar construction and thus members of a class. In three cases (Seychelles, Rockall, Lord Howe) upper mantle velocities ($>8.0 \text{ km s}^{-1}$) are observed at about 30 km below sea level, and immediately above the Moho there is a 14–18 km thick lower crustal layer with seismic P wave velocities in the range $6.0\text{--}7.0 \text{ km s}^{-1}$. Unfortunately, the profiles from the three other plateaus (Mozambique, Saya de Malha, Falkland) do not extend down to the Moho, although the same basal crustal layer is present in Mozambique and Saya de Malha. Still more unfortunately, the Falkland profile does not even reach that far, but is consistent with the others in having a wide range of velocities of up to 6.4 km s^{-1} in its upper parts.

This upper-level velocity variability is also evident in eight seismic profiles from the five platforms suspected not to be of continental origin. But there the resemblance ends. Generally (five profiles — Shatsky, Broken Ridge, Fiji) the mantle is reached at depths of only 18–25 km, and immediately above the Moho there is a lower crustal layer 6–15 km thick having seismic velocities in the range

Peter J. Smith is the Editor of 'Open Earth'.

THE FALLS OF NIAGARA IN WINTER

In the first week of last February it fell to my lot to make very hurriedly the transcontinental journey of 3500 miles from San Francisco to New York. Before starting I resolved that the one stoppage which I could allow myself *en route* should be made at Niagara. I was confirmed in my resolve by seeing statements in various American papers to the effect that, owing to the long-continued and exceptionally severe cold of the present winter, the Ice-mountains at the Falls were higher than had ever been previously known.

In the Niagara gorge numerous springs discharge themselves into the chasm at various points in the precipitous rocky sides, and at these points numerous collections of huge and massive icicles appeared as though adherent to the rock, measuring perhaps seventy or eighty feet in length, and eight to ten feet in irregular diameter.

The boulders in front of the American Fall are, as it were, gigantic nuclei, round which the frozen spray accumulates, and produces the

Ice-mountain of which we hear so much, and the remains of which are not unfrequently to be seen even by summer visitors. The average height of this is about half the total height of the Fall, but this winter it has attained to the unprecedented height of within twenty feet of the top of the Fall!

Within the last few years a considerable portion of "Table Rock" has fallen away. In its present condition a stream of water about one foot in thickness falls over it in summer, and, owing to the amount of its overhanging, it is easy to get between this Fall and the rock, and thus to be "behind Niagara." At the time of my visit (February 8th), however, the whole of this portion of the Fall was *completely frost-bound*. Enormous icicles, of the most surpassing beauty, depended from the rock above, while at my feet were masses of the frozen spray from the Horse-Shoe Fall. The intense emerald green of the water of that Fall, seen through and between these magnificent ice-pendants, could be reproduced by no artist, but will never be effaced from my memory. The accompanying woodcut, photographed on to the wood block from a photographic picture taken a few days prior to my visit, will, to those who know the place, give some faint idea of the beauty of the scene, and of the gigantic scale of the icicles.

From *Nature* **23**, 31 March, 511, 1881.

Gigantic icicle under Table Rock. The upper right-hand corner is rock; a portion of the Canadian (or Horse-Shoe Fall) is on the left. The whole of the apparent ground is a mass of frozen spray which has accumulated many feet in thickness on the shingle at the foot of the rock.

7.3–7.6 km s⁻¹. Then above that there is a unit with typical oceanic layer 3 velocities. The only exception to all this (apart from the Manihiki Plateau whose profile is too short to indicate much) is the Ontong–Java Plateau, the two profiles of which demonstrate a curious mixture of both ‘continental’ and oceanic characteristics. On the face of it, this spoils the story rather, although it could quite genuinely represent a composite structure with both continental and oceanic elements.

Leaving that anomaly aside, however, there are clearly just two basic and distinct structural patterns, suggesting two separate modes of origin. The two types of structure also correlate well with their respective counterparts elsewhere. Thus the first (continental) pattern is very similar to the seismic velocity–depth structure of continental shields, whereas the second (oceanic) is not. Then, the high basal

velocities evident in the second pattern have also been observed at the base of normal crusts in parts of the Pacific and the Atlantic, as well as in some ophiolites, which in fact strengthens the view that oceanic plateaus of the second kind are genuinely of marine origin.

Carlson and his colleagues admit that the number of plateaus for which velocity profiles are available is small and therefore regard their analysis as tentative, although the agreement between the seismic data and prior suppositions about two different origins inspires confidence. The mode of formation of the non-continental plateaus remains open, however. The new analysis seems to confirm the conclusion by Hussong and his colleagues (*J. geophys. Res.* **84**, 6003; 1979) that the truly marine plateaus are expanded sections of normal oceanic crust, but the cause of the expansion is a mystery. □

lymphocytes from many long-standing MG patients make anti-AChR in culture, it seems that the thymus is not the primary site of anti-AChR synthesis (J. Newsom-Davis, Royal Free Hospital, London). Thymic lymphocyte preparations (irradiated to destroy B cells) can also enhance the *in vitro* anti-AChR synthesis by MG peripheral blood lymphocytes, possibly due either to antigenic stimulation by AChR on thymic cells, or to the presence of a thymic helper-T cell population specific for anti-AChR (or both) (Newsom-Davis). Other cell types may also be involved, however, as N. Shinomiya (Tokyo Medical and Dental School) showed that normal, but not MG, peripheral blood T cells inhibited anti-AChR synthesis by MG lymphocytes. This suggests the absence of a specific suppressor-T cell in MG subjects.

This latter finding indicates that even normal subjects may have AChR-sensitive lymphocytes and display low levels of anti-AChR. Anti-AChR has been detected in the sera of 18 per cent of MG relatives (R. Pirskanen, Karolinska Institute) although it did not correlate with HLA-B8, the HLA antigen most closely associated with MG, nor with the electromyographic abnormality also found in a proportion of MG relatives. Others have demonstrated very low levels of anti-AChR in normal subjects (T. Mittag, Mount Sinai School of Medicine), in cultures of normal lymphocytes with MG T cells (R. Kelley, UCLA School of Medicine) and in purified Torpedo AChR (Shinomiya, Tokyo Medical and Dental School). The existence of sensitized B lymphocytes would not be surprising if the normal immune system was exposed to AChR, and it may be relevant that AChR-like molecules have been detected on normal peripheral lymphocytes (G. Morrel, Wayne State University; D. Richman, University of Chicago) and mouse thymic lymphocytes (S. Fuchs, Weizmann Institute) although α -bungarotoxin binding has not been demonstrated.

Work on EAMG may help to elucidate the involvement of genetic factors. When animals are immunized against AChR, a proportion of the anti-AChR antibodies cross-react with the animals’ endplate AChR, resulting in weakness and neuromuscular block. Not all species or strains respond equally and P. Berman (Salk Institute) showed that susceptibility to clinical EAMG in inbred strains of mice was not related to the anti-AChR titre, its ability to increase AChR degradation, or a difference in the safety factor for transmission at endplates from different genetic strains. The greatest susceptibility was found in those with a particular major histocompatibility complex (H-2^b) and immunoglobulin (IgT^b) genotype. The involvement of the IgC_H region suggests that overt myasthenia in mice depends on particular polymorphic genes coding for the constant region of immunoglobulin

Idiotypic restriction in myasthenia gravis antibodies

from Angela Vincent

It is now reasonably certain that anti-acetylcholine receptor antibodies (anti-AChR) play a pathogenic role in the reduction in endplate acetylcholine receptors (AChR) that underlies the defective neuromuscular transmission characteristic of myasthenia gravis (MG). Experimental autoimmune MG (EAMG) in animals immunized against purified AChR, human anti-AChR in over 80% of MG patients, and passive transfer of MG to mice using MG immunoglobulins had all been reported by 1975 and progress made since then was the subject of a recent conference*.

It has been shown that, although in any individual the initial anti-AChR titre gives no indication of the severity of the disease, subsequent anti-AChR levels tend to correlate with changes in the clinical state. Various mechanisms thought to be involved in loss of AChR function have been demonstrated, including complement-dependent damage to the postsynaptic membrane (A. Engel, Mayo Clinic), increased AChR degradation caused by cross-linking of AChR by divalent antibody (D. Drachman, Johns Hopkins University), and direct ‘block’ of AChR function by binding of antibody to the ACh/ α -bungarotoxin binding site (D. Drachman; B. Fulpius, University of Geneva). Antibodies can also modify rather than block AChR function, as E. Albuquerque (University of Maryland)

showed that a factor in MG serum can slightly increase the open lifetime of the individual AChR-associated ion channels. This effect could only be seen, however, when the serum had been applied in the presence of histrionicotoxin, a toxin that reversibly blocks the channel in its open state.

Although the pathogenesis of the disease appears to be established, the fundamental aetiology and cellular immune mechanisms are not. Is there a precipitating event such as virus infection, and how are genetic factors involved? Is there a specific lymphocyte abnormality or a failure of normal control mechanisms? Any answer to these questions must include an explanation of the role of the thymus. Many patients have ‘thymitis’ with germinal centres, and some have a thymic tumour. MG symptoms, particularly in the former group, often respond well to thymectomy although improvement may take months or years. One possibility is that the thymus is the site of both the antigen and the initiating event. It has been recognized for several years that cultured thymic epithelial cells can display muscle-like antigens including AChRs (K. Wekerle, Max Planck Institute). Wekerle proposed that helper-T cells were sensitized to AChR in the thymus and then emigrated to the periphery where anti-AChR synthesis took place. This may well be the case because, although thymic

Angela Vincent is in the Department of Neurological Science, The Royal Free Hospital, London.

*The sixth conference on myasthenia gravis was held in New York from December 2nd to 4th, 1980, organized by Dr D. Grob (Maimonides Medical Center) and sponsored by the New York Academy of Sciences and the Myasthenia Gravis Foundation.

heavy chains. A similar association (with the human Gm allotypes) has been reported in MG (Nakao *et al. Lancet*, 677; 1980). These findings might explain the generally poor correlation between the total anti-AChR titre and disease severity. Clearly, specific subpopulations of antibodies may also be important in MG and will be defined when human monoclonal anti-AChR is available.

In EAMG several workers have used monoclonal antibodies produced by hybridomas to analyse the anti-AChR. A single monoclonal antibody reactive with mammalian AChR can passively transfer EAMG to mice (J. Lindstrom, Salk Institute) or rats (V. Lennon, Mayo Clinic). Surprisingly, antibodies raised in inbred rats against each of three distinct monoclonal antibodies inhibited the activity of the others suggesting that they shared a common idio type (the antigen-specific, hypervariable region) (V. Lennon). However, each anti-idiotypic antibody inhibited only a proportion of the anti-AChR in polyclonal EAMG sera and

when anti-idiotypic-producing animals were immunized directly against AChR they still developed electrophysiological evidence of EAMG.

J. Lindstrom has used monoclonal antibodies raised against intact AChR and its polypeptide subunits to map determinants on receptor extracted from many different species. The main immunogenic region appears to be on the α -subunit of Torpedo and eel AChR and similar determinants are found on AChR from mammals including humans. Three monoclonal antibodies reacting with α , β and γ subunits can bind to human AChR and inhibit the binding of a proportion of human anti-AChR (S. Tzartos, Salk Institute). These results are important because they suggest that the determinants to which human anti-AChR bind are more restricted than was previously inferred from the heterogeneous characteristics of MG anti-AChR (as defined by variability in κ and λ light chains, binding to the α -bungarotoxin binding site, cross-reactivity with other AChR preparations).

Moreover, using a polyclonal anti-idiotypic serum raised in rabbits against human anti-AChR, A. K. Lefvert (Karolinska Institute) has found some sharing of anti-AChR idiotypes between different MG patients.

The treatment of MG has improved since the autoimmune basis for the disease has been widely recognized. Immunosuppressants are used much more freely with good results, and plasma exchange can produce marked temporary improvement. Although several interesting experimental approaches to treatment, including immunization against modified AChR and anti-idiotypic induction in rabbits with EAMG (S. Fuchs), have met with some success, it will be some time before any can be tried in the human disease. Nevertheless, if there is less heterogeneity and greater idio type restriction in MG anti-AChR than previously thought, and if certain idiotypes can be shown to play a crucial role in the disease process, specific immunotherapy may become a realistic goal.

Disposing of dioxins by oxidation

from Alastair Hay

DISPOSAL of waste contaminated by polychlorinated dibenzodioxins (PCDDs) has long been a problem for sections of the chemical industry. Toxic and often remarkably stable, the PCDDs are produced as unwanted by-products during the manufacture of chlorinated phenols.

The best known and most extensively studied PCDD is 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD). It is produced during the manufacture of 2,4,5-trichlorophenol — the starting point for the widely used herbicide 2,4,5-trichlorophenoxyacetic acid (2,4,5-T).

Although pure TCDD is very stable (a temperature in excess of 800°C is required for its thermal degradation), if dissolved in organic solvents such as methanol or benzene it is exceptionally unstable in the presence of ultraviolet light. The solvents act as hydrogen donors, replacing aromatic ring chlorines with hydrogen as TCDD is photolytically degraded. The reaction sequence proceeds in stages with only one chlorine atom being replaced at any one time. Eventually TCDD is degraded to the unchlorinated parent dibenzodioxin (D.G. Crosby *et al. Science* **173**, 748; 1971). Many orders of magnitude less toxic than TCDD, dibenzodioxin too is decomposed by light (J.R. Plimmer *et al. Adv. Chem.* **120**, 44; 1973).

The higher chlorinated dibenzodioxins, hexa-, hepta- and octachlorodibenzo-*p*-dioxin, produced in the manufacture of the wood preservative pentachlorophenol, are also subject to photolytic degradation (C. Rappe *et al. Ann. N.Y. Acad. Sci.* **320**, 1;

1979).

Under field conditions TCDD can be subjected to photolytic degradation by sunlight when a suitable solvent/hydrogen donor is present. When a preparation of the herbicide 'Agent Orange' — a formulation of 2,4,5-T containing 15 p.p.m. TCDD — was exposed to sunlight, the dioxin was rapidly degraded with less than half remaining after 6 hours (A.S. Wong and D.E. Crosby in *Dioxin: Toxicological and Chemical Aspects* (eds Cattabeni, F. *et al.*, Spectrum, New York; 1978). When TCDD was dissolved in an oil/emulsifier mixture and exposed to sunlight, complete degradation occurred within 2 days (A.S. Wong and C.G. Crosby *op. cit.*).

In industry, photodegradation of PCDDs is not very practical and most manufacturers dispose of the chemicals by high-temperature incineration. A method of degradation using chemical processes might provide a more attractive option and in this issue of *Nature* (p.323), D.C. Ayres reports that PCDDs can be degraded efficiently by an oxidative procedure involving ruthenium tetroxide.

Ruthenium tetroxide is a powerful oxidizing agent which reacts with a wide range of organic substances, and according to Ayres, it can be used in solution in water or in organic solvents with no nucleophilic character, such as chloroform, nitro-

methane or carbon tetrachloride. Ayres reports that 2,7-dichlorodibenzo-*p*-dioxin (DCDD) was destroyed by ruthenium tetroxide in carbon tetrachloride solution when the cocktail was allowed to stand overnight at ambient temperature. The rate of oxidation increases with increase in temperature: at 30°C DCDD has a half life of 215 min whilst at 50°C, the half life falls to 38 min. The oxidation of TCDD is a slower process: at 20°C this chemical has a half life of 560 min in the ruthenium tetroxide mixture. At 70°C, however, the half life plummets to a mere 15 min.

Ayres believes that his results demonstrate that ruthenium tetroxide can be safely used for the detoxification of glassware and the periodical purging of industrial reactors to counteract the accumulation of PCDD residues. The process need not be expensive, Ayres claims, for ruthenium tetroxide need only be used in catalytic amounts after which it can be regenerated using a consumable secondary oxidant, such as hypochlorite.

Although Ayres does not know the nature of the fragments formed during the oxidation of the PCDDs, he reports that chlorophenols subjected to ruthenium oxidation undergo extensive decomposition to yield chloride ions and no significant levels of organic products. It remains to be seen whether this is the fate of the PCDDs, but it is clear that oxidation must now challenge incineration as the method of choice for disposing of unwanted polychlorinated dibenzo-*p*-dioxins in industry.

Orbital signature of interglacials

G. Kukla*, A. Berger†, R. Lotti* & J. Brown*

* Lamont-Doherty Geological Observatory of Columbia University, Palisades, New York 10964, USA

† Institute of Astronomy and Geophysics, Université Catholique de Louvain, Louvain-La-Neuve, Belgium

A specific orbital configuration—high obliquity combined with the June perihelion—marked the beginning of the past three interglacials. This suggests that the primary cause of the glacial cycle may be astronomical. An astronomical climate index (ACLIN) is introduced which combines the three orbital variables in the time-lag bivariate model designed to predict the major climate changes in the late and middle Pleistocene, and in the near future. ACLIN closely correlates with the major climatic events revealed by independently dated proxy climate indicators of the past 130,000 yr. It successfully differentiates the interglacials, and displays a 100,000-yr periodicity. It predicts an early end of the present interglacial and the start of a new one in 114,000 yr.

SEVERAL recent observations have shown that the principal periods in the radiometrically dated palaeoclimatic records match in length the periodicities of the Earth's orbit¹⁻⁵. These two systems are probably linked by a cause and effect relationship. Although there have been several attempts to explain the palaeoclimatic record in terms of insolation input, none of the selected palaeoinsolation curves correlates with the different amplitude of interglacials and interstadials. The models simulate the exceptional character of the post-glacial warm interval only when the nonlinear terrestrial response to insolation forcing is included. Different rates of ice growth and decay, a nonlinear isostatic adjustment to the ice-load, thermal memory of the oceans, and so on, represent the terrestrial input^{6,7} (for a review, see ref. 8).

It has been argued, however, that the internal dynamics of the ice sheets can explain the dominant 100,000-yr periodicity of palaeoclimatic records^{9,10} and consequently, that the astronomical modulation of the Earth's climate has, at best, only a secondary role.

We have attempted to test whether the non-linear terrestrial response is necessary to explain the glacial-interglacial cycle. Is there an orbital configuration specific to an interglacial and can the exceptionally warm interglacial climate be explained by orbital configuration alone?

Interglacials are the key climatostratigraphic units recognized in Pleistocene strata worldwide—they reappear about every 10⁵ yr. It is the interglacial environment in which mankind flourished. Any useful prediction of future natural climates has to be able to differentiate between the interglacials and the glacials. If a specific orbital signature of an interglacial was found it would provide: (1) a better understanding of climate; (2) a definition of predictors of future gross climate shifts; and (3) improvement in the dating of past climates.

In this article we first summarize radiometrically dated evidence of climatic changes during the past 350,000 yr; then

compare this record with the history of orbital perturbations and identify orbital configurations, if any, which correlate with interglacials, interstadials and stadials; and finally propose and test an index, based solely on orbital variables, with possible use as a predictor of past and future gross climate states.

Climatic variations of the past 350,000 yr

Past climates were reconstructed from indirect evidence on the size and volume of former ice sheets and on the change in habitats of flora and fauna^{11,12}. Radiometric dates, counts of annual layers and interpolated sedimentation rates provided the time scale. Ocean records are the most complete^{13,14}; land records are the most detailed and the best dated¹⁵. The accuracy of the dating decreases with time. Dating of the past 30,000 yr relies on radiocarbon; it is accurate to within $\sim \pm 1,000$ yr; in the preceding 10,000 yr to within about $\pm 5,000$ yr. Previous to that, because of contamination problems¹⁶, ¹⁴C ages have to be considered minimum values. U/Th isotopic ages give the highest accuracy ($\pm 5,000$ – $6,000$ yr) in the interval between 60,000 and 130,000 yr BP.

Figure 1 summarizes the climate records of the past 130,000 yr. It is based on three sets of proxy climate indicators dated by radiocarbon up to 50,000 yr BP and by U/Th decay series thereafter. The three groups are: (1) Pollen data from Grande Pile, France¹⁷⁻²⁰ and Tenaghi Phillipon, Greece^{21,22}, transferred onto a scale where 100 units correspond to the peak glacial (between 15,000 and 20,000 yr BP) and 200 units to the peak present interglacial (6,000 yr BP). (2) Sea level estimates from dated coral reefs in Barbados²³⁻³⁰, Curacao²⁴, Bermuda^{31,32}, New Guinea³³⁻³⁶, Japan³⁷, Loyalty Islands³⁸, Australia³⁹, Eniwetok Islands⁴⁰, Florida^{24,41} and the Bahamas^{41,42}, and ¹⁴C dated palaeo-sea levels in North Carolina^{43,44}, Scotland⁴⁵, and Australia⁴⁶, transferred on the same relative scale. (3) Delta ¹⁸O records^{3,47-49} in cores RC11-120,

Fig. 1 Climate severity index for the past 130,000 yr based on the three sets of proxy climate indicators (pollen, sea level and $\delta^{18}\text{O}$), expressed on a relative scale where 100 units correspond to the peak glacial and 200 to the peak of the present interglacial. Input data and procedure are explained in text. Horizontal bars show the dating accuracy whereas the envelope gives the range of the climate index values. Note large uncertainty between 20,000 and 70,000 yr BP.

Fig. 2 Orbital signature at the peak (POS) and at the onset (EOS) of major warm and cold episodes of the past 130,000 yr, dated by radioisotopes. The episodes are identified by the age of their peak, given in thousands of years. Vertical scale: climate severity index from Fig. 1. Horizontal scales: longitude of the perihelion (ω) in degrees, obliquity (ϵ) in degrees, and the eccentricity (e). ● mark the episodes with the POS ω from 270° to 360° to 90°. Discussion in text.

METEOR 12392-1, V19-29, and V29-179 dated by correlation with sets 1 and 2 and by Toba Ash⁵⁰, and plotted along the same scale. The index was averaged arithmetically, first within each group and second among groups 1, 2 and 3. In the pollen record from Grande Pile¹⁷⁻²⁰ in France, and Tenaghi Philippon^{21,22} in Greece, the climate index γ was computed after the empirical formula:

$$\gamma = 4x + 2y + z$$

where x , y and z are the warm, cool, and cold principal pollen producing species, respectively, taken as a per cent of the total pollen count. Here x is the sum of oak, fir, hornbeam, alder and hazel; for Grande Pile yew and beech were added; for Tenaghi Philippon Mediterranean hornbeam and pistachio were added. y is the sum of pine, birch and juniper; with spruce added for France, and willow added for Greece. z is grass in France, and the sum of sagebrush and herbs in Greece.

The pollen formula was selected after multiple comparisons of the results with published palaeotemperature reconstructions of the past 130,000 yr (ref. 51). The above formula gave the closest agreement. Details of the procedures will be described elsewhere.

The smoothing process removed the relatively sharp boundaries observed in the land based records^{52,53} separating the cool and the temperate stages. The time series of most proxy climate indicators when inspected on a sufficiently detailed time scale, have a step function form⁵³. They show relatively steady intervals several millenia long, interspersed with short episodes of relatively rapid change. The more recent of these shifts were dated close to 10,000 yr BP (ref. 54), 23,000 yr BP (ref. 55), and 32,000 yr BP (ref. 55). Some such records may result from a step response of a proxy climate indicator with a broad climatic tolerance to a smooth continuous change of climate. However, recent data indicate that the climate over large regions changed in steps^{52,56} along a generally sinusoidal path.

The principal features of the palaeoclimatic history of the past 130,000 yr (shown in Fig. 1) can be summarized as follows. The past 10,000 yr and the interval between ~115,000 and 127,000 yr BP had an interglacial climate, considerably warmer than the rest of the time. There were only two interglacials in the

past 130,000 yr, both began by a pronounced stepwise environmental change accompanying a full scale deglaciation (termination). The most severe part of the last glacial lasted from ~22,000 to ~13,500 yr BP (ref. 57) and continental ice sheets were most extensive between 19,000 and 15,000 yr BP (ref. 58). At that time the sea level was 80 m (ref. 44), and possibly 130 m (ref. 43), lower than today. Similar environmental conditions and, by inference, climate, marked the next-to-last full glacial between 130,000 and 140,000 yr BP (ref. 15). Milder inter-

* Warm interval following or cool interval preceding major deglaciation.

† Values equal or higher than that corresponding to a dated interglacial.

‡ Values equal or lower than that corresponding to the last peak glacial.

Table 2 ACLIN 1 cutoff values

Climate state	ACLIN 1 peak	Duration (kyr)
Interglacial	≥ 4.3	10
Temperate interstadial	$\geq 3.5 < 4.3$	8
Interstadial	$\geq 2.5 < 3.5$	4
Stadial and protostadial	< 2.5	

stadials punctuated the glacial between 115,000 and 22,000 yr BP: the first two episodes are sometimes referred to as temperate interstadials. The environment then locally approached, but globally did not reach, interglacial conditions. Remaining interstadials were cold with arctic climate in the northern middle latitudes. At $\sim 73,000$ yr BP (ref. 14) the climate deteriorated sharply.

As seen in Fig. 1, the climate severity between $\sim 70,000$ and 20,000 yr ago is relatively uncertain. While the deep-sea record and the pollen assemblages in Europe testify to harsh conditions and suggest a large volume of land based ice, the sea level estimates based on raised coral reefs imply a much smaller ice volume.

Palaeoclimates of the interval 130,000–350,000 yr BP are known in much lesser detail and are less accurately dated (Fig. 3). Four interglacials occurred in the past 350,000 yr; each was preceded by one of the major deglaciation dated to $\sim 11,000$, 127,000, 220,000 and 330,000 yr BP. The oldest date is based entirely on interpolated thicknesses of the Brunhes sediments in deep sea cores (ref. 15). Published estimates differ by about $\pm 10\%$. Continuous pollen bearing deposits⁵¹, soil-loess sequences¹⁵, and ^{18}O series⁵⁹ show that the frequency and amplitude of climate oscillations before and after 130,000 yr BP was approximately the same.

Climate index compared with orbital variables

The Earth circumsolar orbit is defined by three parameters:

- (1) The tilt ϵ of the Earth axis to the plane of the ecliptic (obliquity). It varies from $\sim 22^\circ$ to $\sim 24.5^\circ$ within a basic period of $\sim 41,000$ yr. With higher tilt, more insolation is directed to the high latitudes of both hemispheres in summer at the expense of low latitudes.
- (2) The longitude of the perihelion ω . This is measured as the angular distance of perihelion from the autumnal equinox, and defines the season in which the Earth makes its closest approach to the Sun. At perihelion, the intensity of solar radiation reaching the Earth is at a maximum. The precession of the equinoxes, as the process is called, has an irregular periodicity of 13,000–25,000 yr with periods of $\sim 23,000$ yr and 19,000 yr being the most common⁴.
- (3) The eccentricity e is the measure of the Sun's departure from the geometric centre of the Earth's orbit. High eccentricity increases the effect of ω which varies from close to 0 to ~ 0.06 , with periods of $\sim 100,000$ yr and 410,000 yr.

The three orbital parameters at any past or future time can be computed from the equations of planetary mechanics⁶⁸. Although we used recently revised calculations of Berger^{60,61}, the calculations of others agree to about 350,000 yr BP but they diverge further back in time⁶⁰. The precision of the calculations decreases with time due to the limited number of terms used in the expansions and to imprecise knowledge of the input parameters.

Figure 1 gives the timing of the major warm and cold climatic episodes with a wavelength of at least 10,000 yr. It also defines a starting (entry) date of each episode, half way between the neighbouring highs and lows. The orbital signature corresponding to the time of climate peaks, the peak orbital signature (POS), is plotted in Fig. 2a–c. Characteristics of the start of each episode, the entry orbital signature (EOS), is plotted in Fig. 2d–f. Each part of the figure is divided into quadrants defined by the mean values of the climate index and of the corresponding orbital measure.

Figure 2a shows, that mild or warm climatic episodes tend to peak when the longitude of perihelion ω is close to $0^\circ/360^\circ$ (September perihelion), whereas cool episodes culminate near 180° (March perihelion). We therefore label episodes with peak ω between 90° and 270° by open circles and the remainder by full circles. This convention applies throughout Fig. 2. Figure 2b shows that warm climates tend to be associated with high obliquity, and cool climates with low obliquity. Finally, (Fig. 2c) cold climates seem to be associated with low eccentricity.

None of the warm episodes display simultaneously high values of eccentricity, obliquity and autumn perihelion. For instance, the present interglacial peak at 6,000 yr BP has low eccentricity, the 29,000 yr BP interstadial peak has a low obliquity and eccentricity, and the relatively cold episode at 91,000 yr BP has a high obliquity and eccentricity, but a longitude of the perihelion close to 180° .

The orbital configuration disagrees only once with the corresponding climate, at 54,000 yr BP, a time of high obliquity and of autumn perihelion. Although the eccentricity is low, it is not much lower than at the peak of the present interglacial. Why, then, should 54,000 yr BP mark a cold climate? One possibility is that the disagreement stems from poor dating and possible incompleteness of the sea level curve between 40,000 and 65,000 yr BP, which strongly influenced the average index (Fig. 1). Contrary to the master curve, the 54,000-yr BP interval shows a relative amelioration in both the pollen data and the $\delta^{18}\text{O}$ record. However, as no marine terrace of such age is reported, we assume a low sea level between 45,000 and 60,000 yr BP.

Figure 2d–f shows the entry orbital signature as a function of the peak climate index. A phase shift of $\sim 5,000$ – $6,000$ yr exists between the plotted orbital variables and the climate index. The mild and warm episodes show ω close to 270° (June perihelion) whereas cool episodes close to 90° (December perihelion, Fig. 2d). Obliquity values are high during warm episodes and low during cold ones, with the same exceptions as in Fig. 2b. The eccentricity association is similar to Fig. 2c.

Fig. 3 Plots of ACLIN 1 and 2 for the past 350,000 yr and future 150,000 yr. Higher index value correlates with warmer climate. ACLIN 1 interglacial peaks ≥ 4.3 and ACLIN 2 peaks ≥ 0.654 filled in black. Climate severity index for the past 150,000 yr same as in Fig. 1. Mean ages of the U/Th dated coral reefs^{23,24,36,37} shown by dots. Vertical bars show the range of age estimates of terminations (TI–T IV) as obtained from deep sea cores¹⁵. FT I is the first expected future termination. Peaks as high or higher than that of 6,000 yr BP shown by arrow.

We conclude from Fig. 2 that the two interglacials, peaking at 6,000 yr BP and 123,000 yr BP, possess specific orbital characteristics which are absent during the remaining periods. They start at a time of June perihelion and reach a climax at a time of September perihelion, with high obliquity throughout the first half of the interval. Only the interstadial at 82,000 yr BP shows a similar, though markedly weaker character.

To test the correlation of high EOS obliquity with interglacials, all June perihelions ($\omega = 270^\circ$) during the past 360,000 yr BP were listed in Table 1, together with the corresponding obliquity. The known four interglacials started at 335,000, 220,000, 127,000 and 11,000 yr BP. The interglacial starting at 220,000 yr BP shows the lowest EOS obliquity of 23.8° , all three remaining interglacials start with higher values. All interstadials except the one at 292,000 yr BP have an obliquity lower than 23.8° . Thus, at least within the past 250,000 yr, an EOS obliquity of $\geq 23.8^\circ$ together with a June perihelion, is an exclusive characteristic of interglacials. However, this observation does not necessarily imply the existence of a physical mechanism directly linking the two observed properties with terrestrial climates. Some other variable indirectly related in space and time may provide the critical solar-terrestrial link.

It might be expected that the combined impact of high obliquity and of a June perihelion be fully reflected in the insolation values at high latitudes and that a single insolation curve for a selected latitude could serve as a predictor of interglacials. Table 1 shows that this is not the case. Even at the North Pole, where the departures are largest, the insolation at the onset of the postglacial was not any higher than during the four earlier interstadials. The physical explanation of the climatic importance of the high tilt probably lies in the dynamics of the seasonal sea-ice covers. These disintegrate in the late spring and summer as a result of high solar radiation^{62,63}. Only the obliquity cycle, but not the precessional cycle, increases the insolation of the pack ice fields of both hemispheres in phase.

The special importance of the autumn perihelion is linked to the dynamics of snow fields. The seasonal advance of snow fields in autumn has been closely correlated with the seasonal change of insolation⁶⁴, thus snow coverage may be more sensitive to insolation in autumn than during the rest of the year. If so, the autumn perihelion would delay the seasonal expansion of snow in the Northern Hemisphere but would have no measurable effect on the Southern Hemisphere, where seasonal snow fields are negligible.

The astronomical climate index

As shown in Fig. 2, high obliquity, high eccentricity, and autumn perihelion correlate with relatively warm climates. Based on this observation, we formulate an index which would predict a gross climate state as a function of ϵ , ω and e . The resulting astronomical climate index (ACLIN) should be high when ϵ and e is high and when ω approaches 360° . This approach leads to a purely empirical formula, ACLIN 1 (α_1), first introduced in 1978 (ref. 65):

$$\alpha_1 = \left| \frac{\omega_1 - 180}{90} \right| + \epsilon_2 - 22 + \frac{10^3 e_1^2}{2} \quad (1)$$

where α_1 is the climate index at time t_1 , and ω_1 , e_1 the longitude of the perihelion, and eccentricity at a time t_1 , and ϵ_2 the obliquity at a time t_2 , defined by:

$$\omega_2 = \omega_1 - 90 \text{ and } |t_1 - t_2| = \min$$

and where ω_2 is the longitude of the perihelion at a time t_2 . The separation of t_1 and t_2 by 90° in the longitude of the perihelion corresponds to a time lag of $\sim 5,000$ – $6,000$ yr implying a several millenia long memory in the climate system. Plots of α_1 are compared with palaeoclimatic evidence from the past 130,000 yr in Fig. 3, and for the past and future 1 Myr in Fig. 4.

While the correlation of ACLIN 1 with palaeoclimatic evidence is good, the separation of e and ω in two independent

variables disagrees with the laws of orbital geometry. An improved ACLIN formula therefore takes into account the physical link between orbital perturbation and insolation. It is composed of two terms: A , proportional to the relative intensity of ground level insolation at high latitudes at the summer solstice, and B , proportional to the relative intensity of insolation at the autumnal equinox.

$$A = \sin \epsilon \frac{1 + 2e \cos(\omega + 90)}{(1 - e^2)^2} \quad (2)$$

$$B = \frac{1 + 2e \cos \omega}{(1 - e^2)^2} \quad (3)$$

Both A and B are scanned at the same times t_1 and t_2 as in ACLIN 1. Other separations of t_1 and t_2 are possible but have not been investigated (see ref. 6). The present arbitrary selection of t_2 as used in all ACLIN formulas was based on the good correlation of EOS with the climate index. As the orbital variables are scanned at two different intervals, ACLIN is a time-lag bivariate model.

The basic ACLIN formula has the simplified form

$$\alpha_0 = a(A_1 + b \cdot B_1) + (A_2 + c \cdot B_2) \quad (4)$$

and can be written in full as

$$\alpha_0 = a \frac{\sin \epsilon_1 [1 + 2e_1 \cos(\omega_1 + 90)] + b(1 + 2e_1 \cos \omega_1)}{(1 - e_1^2)^2} + \frac{\sin \epsilon_2 [1 + 2e_2 \cos(\omega_2 + 90)] + c(1 + 2e_2 \cos \omega_2)}{(1 - e_2^2)^2} \quad (5)$$

Fig. 4 Plot of ACLIN 1 from 1,000,000 yr BP to 1,000,000 yr AP. Higher value indicates warmer climate. Peak Holocene (A) level of ≥ 4.3 defines interglacials marked with arrows. Past peak glacial level at about 17,000 yr BP (B).

where α_0 is the ACLIN index for time t_1 , $e_1, \varepsilon_1, \omega_1$ the orbital elements at a time t_1 and $e_2, \varepsilon_2, \omega_2$ the orbital elements at a preceding interval t_2 defined in the same way as in ACLIN 1, and a, b and c the arbitrary coefficients.

Various versions of α_0 were studied. Best results were obtained with ACLIN 2 (α_2), in which $a = b = 0.25$ and $c = a^2$. A plot of ACLIN 2 is shown in Fig. 3.

The following criteria have been applied to test the predictive merits of ACLIN variants:

Accuracy level 1: predicts 10 interglacials in the past Myr, spread at $\sim 10^5$ yr intervals, it also fulfills criteria for level 3.

Accuracy level 2: predicts interglacials in the past 350,000 yr at times matching palaeoclimatic records within the accuracy of radiometric dating. Predicts temperate interstadials (and not interglacials) at $\sim 80,000$ and $100,000$ yr BP and the relative amplitudes of cold minima at $\sim 18,000, 65,000$ and $110,000$ yr BP.

Accuracy level 3: predicts the relative amplitude and timing of interglacials and temperate interstadials during the past 150,000 yr and the timing but not the relative amplitude of the cold peaks.

Accuracy level 4: predicts correctly the relative timing but not the amplitude of warm and cold intervals during the past 150,000 yr. Does not predict interglacials.

No solution has yet been found reaching accuracy level 1. ACLIN 1 is the only formula tested so far which reached accuracy level 2. Formula ACLIN 2 reached accuracy level 3. Additional ACLIN variants can be constructed to obtain a better agreement with palaeoclimatic records, following the tuning strategy proposed by Imbrie and Imbrie⁸. However, the two described versions are sufficiently successful to be used for long range climate estimates.

ACLIN time series approach a smooth sinusoidal function. A computer program can transform ACLIN into a stepwise form, scanning for maxima and minima (Table 2), and assigning a parametrized duration to the three mild climate states. In such a model, protostadials and stadials occupy the rest of the time. Protostadials are gross cold climate episodes characterized by a restricted size of continental ice sheets which occur within the first 50,000 yr or so of an interglacial-glacial cycle.

Figure 5 shows the spectral response of ACLIN 1 and ACLIN 2 compared with amplitude spectra of the deep sea core V28-238 and the spectrum of Imbrie and Imbrie's model. ACLIN 2 has significant peaks only at periods of $\sim 41,000$ yr (the obliquity cycle) and $\sim 23,000$ and $19,000$ yr (the precession cycle) whereas ACLIN 1 shows an additional significant peak near $100,000$ yr. Although the $100,000$ -yr peak in ACLIN 1 is not as dominant as it is in the oxygen isotope record of core V28-238, we find the ACLIN 1 result encouraging. It shows that a bivariate model based solely on the orbital input is capable of generating a $100,000$ -yr cycle. In ACLIN this period is due to the eccentricity, but the real cause is the coupling of high obliquity and precession modulated by the eccentricity (see Table 1).

The spectrum of ACLIN 1, based entirely on orbital variables, closely resembles the spectrum of Imbrie and Imbrie's model⁸ in which nonlinear ice growth rates were combined with an insolation function. Similar to Imbrie's model, ACLIN 1 has a power in the $400,000$ -yr range but with a lower and more realistic peak.

Discussion

Given the complexity of the Earth-atmosphere system, it is surprising that the simple ACLIN formulae successfully simulate the principal features of the palaeoclimatic record. This emphasizes again the dominant role of orbital variations in the shaping of past climates. The most significant achievement of ACLIN is the successful discrimination of interglacials on the sole basis of orbital input scanned across a $\sim 5,000$ -yr interval. All earlier models had to include a nonlinear response of the terrestrial system to orbital forcing to separate the interglacials and generate the $100,000$ -yr periodicity.

Fig. 5 Power spectra of the oxygen isotope record in the Pacific core V28-238 over the past 730,000 yr (ref. 59); the output of the Imbrie and Imbrie non-linear climate model⁸ for the past 1,000,000 yr; the ACLIN 1 model over the past 1,000,000 yr; and the ACLIN 2 model over the same interval. Observe a $\sim 100,000$ and $\sim 410,000$ yr peak present in the ACLIN-1 and in the Imbrie model, but missing in ACLIN 2.

While utmost caution is needed in the interpretation of our data⁸, the results have some implications for climate theory:

- (1) The gross climate state may almost be in equilibrium with orbital forcing. Otherwise, it would seem impossible to predict interglacials solely from the orbital configuration of a $\sim 5,000$ yr long interval.
- (2) The primary origin of the $100,000$ yr cycle can be orbital rather than terrestrial. If this is so, a primary orbital forcing would be modulated by a nonlinear thermal, mass, and isostatic response of ice and oceans, rather than the reverse.
- (3) Increased insolation to high latitudes at the expense of low latitudes is associated with warm global climates, not the other way around.
- (4) The interaction of both hemispheres, not the sole dominance of the Northern Hemisphere, seems to be critical in the dynamics of the $100,000$ yr cycle. This is indicated by the dominant role of obliquity in the ACLIN formula. (It had been suggested earlier^{1,2} that the tilt may have played a principal role in shaping the past climates.)
- (5) The seasonal pack-ice in both hemispheres and the snow fields in the Northern Hemisphere seem to play a key part in the dynamics of Pleistocene climates as suggested earlier^{62,66}.

While the ACLIN simulates the relative intensity of mild events quite well, it does not reproduce the cold episodes very well. For instance, the $133,000$ -yr BP ACLIN 1 value is considerably higher than that for $17,000$ yr BP, while the extent and the volume of continental ice was approximately the same at both intervals. Interglacials indicated by proxy data at $\sim 400,000$ and $500,000$ yr BP, are also poorly reproduced by ACLIN. ACLIN peaks at corresponding times do not reach the

4.3 cutoff level. However, the accuracy of both geological and astronomical data before 350,000 yr BP is low.

The general agreement of the ACLIN time series with the reconstructed palaeoclimates permits future gross climate states to be predicted. Such an estimate, however, can only be valid if man's impact on the land and the atmosphere has not significantly modified the mechanism of climate change, and will not do so in the future.

The ACLIN time series is extrapolated into the future in Figs 3 and 4. Both α_1 and α_2 predict a considerably cooler climate for the next 114,000 yr, followed by an interglacial. The first cold peak with a period of 10,000–100,000 yr should occur 4,000 yr AP (after present). ACLIN 1, but not ACLIN 2, predicts an amelioration around 15,000 yr AP followed by a cold interval centred around 23,000 yr AP. This agrees with the

prediction of Berger *et al.*⁶⁷ and Imbrie and Imbrie⁸. A major glaciation, comparable to stage 4 of the last glacial cycle, is indicated at 60,000 yr AP.

Our approach can predict at best only a very approximate general framework of gross climate changes. Detailed climate reconstructions or predictions will have to consider interactions of orbital perturbations with changing solar activity and with natural and manmade variables of terrestrial origin.

We thank J. Imbrie for innumerable improvements as well as for Fig. 5 data, and N. Shackleton, K. Bergman, J. Hays, and W. S. Broecker for reading the manuscript. Research was supported by NSF grants ATM77-28522 and ATM80-01470, and the Office of Nuclear Waste Isolation, managed by Battelle Memorial Institute for the Department of Energy under contract DE-AC06-76-RLO-1830.

A carbon budget for overfishing off Peru

John J. Walsh

Oceanographic Sciences Division, Brookhaven National Laboratory, Upton, New York 11973, USA

The rise and collapse of the Peruvian anchovy fishery between the 1950s and the 1970s was accompanied by marked changes in the fluxes of a carbon budget for the upwelling ecosystem.

THE anchovy harvest off the coast of Peru increased from 700,000 tonnes yr⁻¹ in 1958 to a maximum of ~12 million tonnes yr⁻¹ in 1970, but then declined precipitously to ~2 million tonnes yr⁻¹ in 1973 and to ~1 million tonnes yr⁻¹ between 1977 and 1979. The collapse of the anchovy fishery, located in the upwelling ecosystem off the coast of Peru, is attributable to overfishing and the diminished survival of anchovy larvae during warm-water intrusions (El Niños) southwards along the coast of Peru in both 1972 and 1976¹.

The very large yield of anchovy (*Engraulis ringens*) in the heyday of the fishery is usually attributed to high primary production in the upwelling system and the high efficiency of the

food chain in which the commercial fish feed directly on phytoplankton. In reality, there has been debate^{2,3} for more than a decade about the relative importance in the maintenance of the anchovy stocks of the short food web (phytoplankton → anchovy) with ~10% ecological efficiency and of a longer food web (phytoplankton → zooplankton → anchovy) with efficiency of ~1% but functioning over an area perhaps 10 times as great. A primitive simulation⁴ of the daily nitrogen flux through the Peruvian upwelling system suggested that the longer and more widely spread food-web might be more important during the strong winter upwelling off Peru. A clearer understanding of the trophodynamics of the upwelling system is now possible by

Fig. 1 A budget for the flux of carbon ($\text{g C m}^{-2} \text{yr}^{-1}$) through the Peru food web: a, before (~1966-69) and b, after (~1976-79) overfishing of anchovy.

examining the annual carbon budgets before and after overfishing, in the periods 1966-69 and 1976-79 respectively. The 1966 primary production data (Table 1) are high because they were collected while the ship was drifting within a high chlorophyll area at the shelf-break⁴. The March-April 1976-77 data are low because repeated time series stations were taken within a low chlorophyll area near the coast¹. Other data in Table 1 were averaged from transects taken across the shelf. High chlorophyll and abundant anchovy eggs are found within 50 km of the coast¹, suggesting that a combined productivity average of this region is a reasonable estimate of the yearly carbon input to the Peru upwelling food chain. At a rate of at least $3 \text{ g C m}^{-2} \text{day}^{-1}$ ($\bar{X} = 4 \text{ g C m}^{-2} \text{day}^{-1}$ in Table 1), the annual primary production is a minimum of $\sim 1,000 \text{ g C m}^{-2} \text{yr}^{-1}$ off Peru (see Table 2) in contrast to $\sim 200\text{--}500 \text{ g C m}^{-2} \text{yr}^{-1}$ for shelf ecosystems at higher latitudes⁵.

An upwelling zone of $\sim 50 \text{ km}$ offshore width, extending along the Peru-Chile coast of $\sim 2,000 \text{ km}$ length ($4\text{--}22^\circ\text{S}$), and a peak fish catch of 10 million tonnes yr^{-1} harvested over the whole area ($1 \times 10^5 \text{ km}^2$) suggests a yield of at least 100 tonnes $\text{km}^{-2} \text{yr}^{-1}$. Such a harvest was an order of magnitude higher than that presently derived from the North Sea, the Mid-Atlantic Bight or the Bering Sea⁵. With a conversion factor of $0.06 \text{ g C} = 1 \text{ g ww}$, a harvest of 100 tonnes $\text{km}^{-2} \text{yr}^{-1}$ ($100 \text{ g m}^{-2} \text{yr}^{-1}$) suggests, however, a yield to man of only $6 \text{ g C m}^{-2} \text{yr}^{-1}$ of anchovy off Peru from a primary production of at least $\sim 1,000 \text{ g C m}^{-2} \text{yr}^{-1}$. As man was the major consumer of the anchovy during its peak and declining yields, this harvest may be a reasonable estimate of fish secondary production over the

whole region. It suggests a food chain efficiency of $< 1\%$ before the fishery collapsed. The yield from the anchovy fishery in 1976-79 was ~ 1 million tonnes yr^{-1} , or an implied food chain efficiency to man of only 0.1% after overfishing if the catch then also approximated secondary production of the anchovy.

The same maximum estimate of secondary production, taken from a 90% smaller upwelling region, would represent a larger yield to man per unit area—a greater implied food chain efficiency. For example, if most of the peak yield had been derived only from the area of high anchovy egg and larvae abundance¹, north of Callao on the broad shelf between 6 and 10°S , then the annual harvest would have been $60 \text{ g C m}^{-2} \text{yr}^{-1}$ of fish before overfishing occurred (Table 2). If the anchovy in this area also consumed phytoplankton half the year and zooplankton with a growth efficiency of 20% (Table 2) during the other half of the year⁶, the fish yield would then have been 10% of their food input from this smaller region between 6 and 10°S . A more detailed carbon budget for the food web off Peru may determine the fate of the primary production along 90% of the Peru coast before overfishing, if most of the annual yield was derived from facultative herbivorous fish within an area of only $1 \times 10^4 \text{ km}^2$.

Carbon budget off Peru

Information on oxygen content, particle fluxes to the bottom, sea-bed respiration, organic content of the sediments and nutrient depletion of the water column aid in the construction of a more complete carbon budget before (Fig. 1a) and after overfishing (Fig. 1b). Previous analysis of the demersal part of

the nearshore food chain before overfishing suggested that the input of carbon to the bottom consisted mainly of faecal pellets rather than phytodetritus⁴. In terms of carbon consumption, the decomposition of the faecal pellets could be attributed to caprophagy and/or bacterial activity in both the water column and sediments. Additional calculations⁷ had indicated that the oxygen demand of this detrital carbon flux was such that most of the faecal pellets could be remineralized within the upper 60 m of the water column. After overfishing and the decline of grazing pressure from adult anchovy, however, a large flux of phyto-detritus may have sunk out of the water column when nutrient depletion occurred at the edge of the shelf.

The estimate for bacterioplankton production (Table 2) from consumption of faecal pellets within the upper part of the water column before overfishing (Fig. 1a) was obtained from a steady-state budget of the vertical decline of oxygen at 15°S in 1966–69; 4.5 ml O₂ l⁻¹ above 20 m and 0.5 ml O₂ l⁻¹ below⁷. As a result of oxygen depletion in upwelled source water during March to April 1976, 1977 and 1978, however, the average O₂ concentration at 15°S was ~1 ml O₂ l⁻¹ in the upper 20 and 0.5 ml O₂ l⁻¹ below, that is a vertical gradient of ~0.04 ml O₂ l⁻¹ m⁻¹ after overfishing in contrast to 0.4 ml O₂ l⁻¹ m⁻¹ a decade earlier. The local production of aerobic bacteria was thus estimated to be an order of magnitude less (Table 2) in the low chlorophyllic surface waters of the second carbon budget (Fig. 1b) with the remaining detrital carbon then sinking to where more denitrification⁸ occurred in deeper water and sulphate reduction⁹ in the bottom sediments.

Table 1 Mean daily primary production in Peru Shelf waters from 1966 to 1978

Year	g C m ⁻² day ⁻¹	(N)	Month	Area	Ref.
1965	6.3	(15)	March–April	15°S	35
1969	5.2	(32)	March–April	15°S	35
1969	1.3	(12)	June	10–15°S	4
1974	4.5	(5)	February–March	7–8°S	19
1975	3.8	(5)	March–May	6–12°S	36
1976	3.2	(4)	August–September	10–15°S	1
1976	1.7	(29)	March–April	15°S	35
1977	1.9	(43)	March–April	15°S	35
1977	7.3	(10)	November	9–10°S	18
1978	4.3	(30)	March–April	15°S	35

$$\bar{X} = 3.95.$$

The aerobic carbon production of the benthos before overfishing (Fig. 1a) was estimated from both P/B estimates and bottom respiration measurements at 15°S in March to April 1969¹⁰. The mean macrobenthos biomass across the shelf in 1969¹¹ was 0.5 g C m⁻², suggesting a secondary production of 0.5 g C m⁻² yr⁻¹ (Table 2) and an ingestion demand of 5.0 g C m⁻² yr⁻¹ from a P/B ratio of 1 and a growth efficiency of 10%. Approximately 20% of the measured ~25 g C m⁻² yr⁻¹ bottom respiration¹⁰ might thus be due to macrobenthos off Peru in 1969. The rest is attributed to micro- and meio-benthos as in the bottom metabolism of other shelves^{12,13}.

The total input of carbon to the shelf bottom before overfishing (Table 2) is similar to a flux of 88 g C m⁻² yr⁻¹ at 50 m measured with floating sediment traps on the narrow shelf at 15°S in 1977⁹. If a higher sinking loss was applied (without other losses) to an early model of the nearshore Peru upwelling system¹⁴, the predicted amount of downstream chlorophyll in the offshore region was less than that observed. The nearshore area at 15°S contained the same amount of low chlorophyll (<2 µg l⁻¹) during 1966, 1969, 1976, 1977 and 1978, as that found inshore at 10°S during 1960–69 and 1976–77, suggesting that an estimate of a sinking loss of only 10% of nearshore primary production is reasonable, as higher phytoplankton biomass is found downstream, that is, offshore.

The production of the benthic food web after overfishing (Fig. 1b) was first estimated from sulphate reduction estimates of 90 g C m⁻² yr⁻¹ for anaerobic metabolic demand at 15°S in

surface sediments⁹. The sulphur bacterium, *Thioploca*, was found on the bottom in large numbers along the whole Peru coast during 1976, and the near bottom oxygen concentration at 15°S on the 100-m isobath was <0.1 ml O₂ l⁻¹ in 1976–77, compared with ~0.2–1.0 ml O₂ l⁻¹ in 1969. The content of the secondary nitrite maximum increased from 3–6 µg-atom NO₂ l⁻¹ in 1966–69¹⁵ to 14 µg-atom NO₂ l⁻¹ in 1977⁸. Similarly no sulphate reduction was detected in the water column in 1969¹⁶ at 15°S, whereas H₂S was found there in March to April 1976¹⁷ and at 8–9°S during November 1977¹⁸. Based on an average 1977 meio-benthic biomass of 0.6 g C m⁻² across the shelf⁹ and a P/B ratio of 4/1 reflecting a higher turnover rate of these small organisms, the secondary production of the meio-benthos might have been 2.5 g C m⁻² yr⁻¹ (Table 2), 28% of the sulphate reduction estimate of microbial production. Quantitative macrobenthic data are not available for 1976–78 but their biomass and production (Table 2) were then presumably smaller because more extensive anoxic conditions occurred on the Peru shelf.

As the primary electron acceptor in the oxidation of organic matter in the sea is oxygen, then nitrate in the process of denitrification, and finally sulphate reduction, the above sequence suggests that a larger than normal organic loading to the bottom of the shelf and upper slope had occurred by 1976–77 (Fig. 1b). The total detrital flux from the water column after overfishing in 1976–79 is, in fact, estimated (Table 2) to be 70% of the 1,000 g C m⁻² yr⁻¹ primary production. After the 1976 El Niño, such a detrital loss (Fig. 1b) is almost an order of magnitude larger than that estimated for 1966–69 (Fig. 1a), but similar to an estimate of 64% detrital loss¹⁹ in 1974 at 7–8°S after the 1972 El Niño. Within the geological record, a 10-fold increase in sedimentation rate is associated with a doubling of the organic carbon content of the sediments²⁰. If the above carbon budgets are correct, a similar process may have occurred off Peru from 1966–69 to 1976–79.

The distribution of organic carbon in the surface sediments (Fig. 2) suggests that before overfishing in 1968 and 1969^{11,21,22} the sediment carbon off Peru increased both seawards at the slope and polewards. Without consideration of changes in food chain dynamics, a primary production rate of 1,000 g C m⁻² yr⁻¹ and a previous sedimentation rate of 0.1 cm yr⁻¹ can be calculated²⁰ as a carbon accumulation rate within the sediments of 114 g C m⁻² yr⁻¹ off Peru, that is similar to that from the carbon budget before overfishing (Table 2). The location of the 2% carbon isopleth in the sediments of the wide shelf north of Callao in 1968–69 (Fig. 2) also suggests that less carbon used to be lost from the water column at 10°S than 15°S. These spatial trends continued after overfishing in 1976 (C. Delgado, L. A. Flores and G. T. Rowe, unpublished data) and 1977^{18,23}, but the carbon content of the surface sediments may have doubled recently. The same primary production and a sixfold increase in sedimentation rate (Table 2) lead to an empirical carbon accumulation rate²⁰ of 684 g C m⁻² yr⁻¹ in the sediments compared with that of 591 g C m⁻² yr⁻¹ estimated from the overfishing budget (Fig. 1b).

At 15°S, 4.5% carbon was the highest surface sediment value observed on the shelf in March to April 1969¹¹, but 10% carbon was found at the same stations with the same methods in 1976. Furthermore, within 22 cores taken across the 15°S Peru shelf and slope in 1977–78, the mean subsurface C/N value at 50 cm depth of these cores was 7.76 compared with 7.53 in the surface sediments, suggesting little diagenetic change²⁴. However, the mean % carbon was 2.89 at 50 cm depth and 4.82 at the surface, implying a recent increase in carbon flux to the sediments that could have occurred within the past decade. Inadequate spatial sampling means that areas of high organic content may have been missed in these 1968–78 surveys, but the horizontal, temporal and vertical trends of the sediment carbon data are at least consistent with the carbon budgets of the water column. The first carbon budget (Fig. 1a) for the food web before overfishing may be most applicable to northern Peru waters during 1966–69. The second budget (Fig. 1b) may instead reflect

the food web both before overfishing off southern Peru and afterwards off northern Peru.

The predicted change in dominance of pelagic and demersal fish species after overfishing (Fig. 1b) reflects the decline in these budgets of anchovy ingestion demands on both phytoplankton and zooplankton⁶. The increase of zooplankton biomass after the 1972 and 1976 El Niños was mainly in the standing stocks of omnivorous euphausiids^{1,19}. In contrast, there was little apparent change in their biomass after the 1957 El Niño²⁵, when the anchovy fishery was just beginning. The sardine, *Sardinops sagax*, and hake, *Merluccius gayi*, both eat zooplankton off Peru, suggesting that the stocks of these fish should also increase after the anchovy decline. Similar changes occurred in demersal species abundance within the North Sea after the pelagic fish stocks were overfished²⁶.

Following the 1976 El Niño, sardine indeed constituted ~67% of the pelagic yield of 1.5 million tonnes yr⁻¹ in 1977. During 1978 and 1979, the catch of mackerel, sardine, pipefish, and horse-mackerel was still ~50% of the total pelagic yield of 1–2 million tonnes yr⁻¹. Furthermore, the potential demersal yield of 'virgin' hake stocks was estimated to be 0.75 million tonnes yr⁻¹ after the 1972 El Niño²⁷. This is similar to the change predicted in the second carbon budget (Fig. 1b) of a yield of 0.71 g C m⁻² yr⁻¹, or 1.2 million tonnes yr⁻¹ of demersal fish along the whole coast (1 × 10⁵ km²). Despite restrictions in fishing, however, the same amount of plankton was not consumed by euphausiids, sardine, mackerel and hake in 1976 as by anchovy in 1966. Instead, the oxygen content of the euphotic zone and sea bed has since declined, the nitrite and sulphide content of the water column increased, and the organic content of the bottom sediments also apparently increased after overfishing.

Nitrogen mass balance for carbon fluxes

If 10³ tonnes km⁻² yr⁻¹ of anchovy had been produced on the wide shelf north of Callao (1 × 10⁴ km²) and 10² tonnes km⁻² yr⁻¹ along the rest of the coast (9 × 10⁴ km²), the combined secondary production of 19 million tonnes yr⁻¹ before overfishing is the same as that originally estimated in 1969^{2,3}. The carbon budget for the Peru food chain after overfishing (Fig. 1b) is thus a more reasonable description of the food chain along most of the Peru coast before and after overfishing with the exception of the 6–10°S area. If this second budget did apply to 15°S during 1966–69 (before overfishing), then about half of the daily production of phytoplankton was always lost as sinking detritus to the upper slope after nutrient depletion within offshore waters²⁸ rather than cropped inshore by zooplankton and anchovy^{4,29}. Annual carbon budgets of the shelf food webs of the Mid-Atlantic Bight⁵, the Gulf of Mexico and the Bering Sea similarly suggest that ~50% of their primary production

Table 2 Changes in annual carbon fluxes of the Peru upwelling ecosystem between 1966–69 and 1976–79

* Measured; † calculated.

may be exported to the continental slope as phytodetrital carbon from these shelves, thus constituting a major organic sink of the global CO₂ budget³⁰.

An annual detrital carbon loss of ~500 g C m⁻² yr⁻¹ at 15°S, and a C/N ratio of 5/1 implies that the particulate nitrogen export in the form of detritus is 100 g N m⁻² yr⁻¹, in contrast to ~1 g N m⁻² yr⁻¹ in the form of fish yield (Fig. 1b). To maintain a nitrogen mass balance in an annual steady state of the food web on this Peru shelf, ~100 g N m⁻² yr⁻¹ of dissolved nitrogen must at least be returned to the shelf to replace the detrital and fish nitrogen loss. Furthermore, an annual primary production of ~1,000 g C m⁻² yr⁻¹ at 15°S requires 200 g N m⁻² yr⁻¹, 40% of which could be supplied by uptake of ammonium from nitrogen recycling³¹ and 60% by physical input of nitrate from upwelling, because river runoff is negligible²⁴. An estimate of the nitrate supply can be made with a simple budget, $\delta\text{NO}_3/\delta t = w\delta\text{NO}_3/\delta z$, using an average upwelling rate, w , of 10 m day⁻¹ and an observed vertical nitrate gradient of 5 mg-atom NO₃ m⁻³ over the 50-m depth interval of the nearshore upwelling region off Peru⁴; this daily flux sums to 5 g NO₃ m⁻³ yr⁻¹. Over a 20–30-m euphotic zone, such an input of 100–150 g NO₃ m⁻² yr⁻¹ would be sufficient to balance the 'new' nitrogen demands³² of photosynthesis, fish removal and detrital loss from the shelf at 15°S.

Similar to recent changes in North Sea herring stocks²⁶, a 90% decline of anchovy production from 60 to 6 g C m⁻² yr⁻¹ off northern Peru as a result of overfishing, however, would lead to a much larger absolute change in the detrital carbon (nitrogen) flux at 10°S (a Δ of ~500 versus ~20 g C m⁻² yr⁻¹) than a similar percentage reduction from 6.0 to 0.6 g C m⁻² yr⁻¹ at

Fig. 2 The distribution of % organic carbon in the surface sediments along the Peru coast in a, 1968–69, $N = 63$; b, 1976, $N = 97$; c, 1977, $N = 56$.

15°S. The subsurface flow of water off Peru is to the south at $\sim 1\text{--}5\text{ cm s}^{-1}$ within the Peru–Chile undercurrent at the edge of the shelf. With these differences in area, food chain efficiency, and yield, the total poleward, or downstream, detrital load of the Peru system could have approximately doubled after overfishing of the anchovy stocks between 6 and 10°S. Thus part of the apparent bottom carbon transient after overfishing at 15°S, that is, a doubling between 1968 and 1978 could be the result of sinking detritus advected south within the Peru–Chile undercurrent. If the 1966–69 anchovy grazing pressure were reapplied to the shelf ecosystem at 6–10°S, presumably the upstream source of phytodetritus would decline, and the per cent sediment carbon at 15°S might also decline if the accumulated surficial bottom carbon were oxidized or further exported to the continental rise^{24,30}. Based on ²¹⁰Pb dating, cores taken at 186–370 m depth between 11 and 13°S in June 1977 suggest a sedimentation rate of 0.05–0.16 cm yr⁻¹ off northern Peru³³, whereas cores taken at 82–250 m depth near 15°S in February–March 1978 indicate a rate of 1.1–1.2 cm yr⁻¹ off Southern Peru³⁴.

Conclusions

Although the estimates in these carbon budgets are questionable it seems that most of both the larval survival and harvest of adult anchovy used to occur within a 10% area of the Peru shelf. This is about the same per cent area of the Bering Sea from which most stocks of the Alaska pollock are harvested⁵. The

hypothesis that greater changes in shelf trophodynamics have occurred within the 6–10°S area than in the 15°S region seems to reflect the impact of both overfishing by man and alteration of larval survival by nature off Peru¹. The decline of anchovy grazing pressure has apparently led to increases in plankton biomass, increased stocks of sardine and hake, increased carbon loading and sulphate reduction at the 'downstream' sea bed, and a decline in oxygen and nitrate content of the water column.

Although the anchovy fishery of the Peru upwelling ecosystem was one of the world's most 'studied', 'advised' and 'managed' coastal resource, societal conflicts led to its possible demise. Along the whole coast, the fish yield may now be only 10 tonnes km⁻² yr⁻¹, similar to that from the Mid-Atlantic Bight, North Sea and Bering Sea despite a three- to sevenfold higher primary production off Peru. Future studies will determine whether after these changes in carbon export, the carrying capacity of this system with respect to living resources will remain at present level. It is possible that the Peru upwelling ecosystem will either return to the same level of secondary production before 1972, or maintain the present decline in food chain yield such that the greater export in the form of detrital carbon rather than of fish carbon will continue.

The data collection and reduction phase of this research was supported mainly by the NSF as part of the Coastal Upwelling Ecosystem Analysis and Process and Resources of the Bering Sea programs. Additional data analysis was supported by the DOE as part of our Atlantic Coastal Ecosystem program. Drs G. Rowe and E. Suess provided sediment carbon data.

In vivo sequence requirements of the SV40 early promoter region

Christophe Benoist* & Pierre Chambon

Laboratoire de Génétique Moléculaire des Eucaryotes du CNRS, Unité 184 de Biologie Moléculaire et de Génie Génétique de l'INSERM, Institut de Chimie Biologique, Faculté de Médecine, 67085 Strasbourg, France

To investigate the sequences necessary for proper initiation of transcription of SV40 early genes, we have constructed several deletion mutants in the promoter region. The TATA box region is apparently involved in fixing initiation precisely within a narrow area, but is dispensable for gene expression, while the sequences located more than 150 base pairs upstream are indispensable.

IN eukaryotic systems, the identity and even the existence of the DNA sequences which function as promoters for RNA polymerase B are as yet uncertain. DNA sequences of eukaryotic

genes (see refs 1, 2 for reviews) and their adjacent regions nevertheless contain an A+T-rich region, typically 5'TATA_AT_A3' at a strongly conserved distance 30 base pairs from the nucleotide coding for the first base of the mature mRNA, called the cap site and presumably the point at which transcription begins³. The A+T-rich region, known as the

* Present address: Stanford University Medical School, Department of Genetics, Stanford, California 94305, USA.

Fig. 1 a, Scale in SV40 map units (above the line) or in base pairs (bp), the latter according to the numbering system¹³ of Reddy *et al.*⁴¹ modified to take into account a previously overlooked 17 base pairs²⁹. b, Physical map of the SV40 early promoter region in the pSV1 recombinant¹³, and schematic representation of the deletions present in some of the mutants analysed in this study. SV40 sequences are represented by a solid line, pBR322 sequences by a dashed line. Sal, Hind, Eco, Pvu, Bgl, Hinf, RII and Taq represent sites for restriction enzymes *Sal*I, *Hind*III, *Eco*RI, *Pvu*II, *Bgl*I, *Hinf*I, *Eco*RII and *Taq*I, respectively (only the relevant sites are shown). *Eco*RII indicates the *Eco*RI site of pSV1 created by the blunt-end ligation of the repaired SV40 *Hpa*II site into the repaired *Eco*RI site of pBR322¹³. The position of the 5' ends of wild-type SV40 early mRNAs are shown by vertical lines, followed by a horizontal arrow which indicates the direction of transcription [+1 corresponds to the first cap site at position 5,172 (refs 19, 20)]. The position of ATG translation initiation codon is shown next to the restriction site *Hind*2. The small solid box indicates the position of the TATA box (position -21 to -27 from position +1). Large boxes represent the 72-base pair repeats I and II, and the dashed areas within correspond to the G+C-rich blocks. The three small dashed boxes are the shorter, G+C-rich repeats (see Fig. 2a). The position of the deletions in mutants P1A and AS is shown under the *Bgl*I site. Horizontal arrows define the extent of the deletions, as determined by DNA sequence analysis, in representative HS and PS mutants. For the construction of P1A, pSV1 was linearized by partial cleavage with *Bgl*I (there are three *Bgl*I sites in the pBR322 portion of pSV1 along with the unique site of interest in the SV40 moiety). The *Bgl*I 3'-protruding extremities were removed with *Escherichia coli* DNA polymerase I (Biolabs), and the plasmids circularized by blunt-end ligation with T4 DNA ligase. P1A was isolated by screening recombinants for the absence of the *Bgl*I site in the SV40 sequences. The deletion in P1A led to the generation of a *Sac*II site at this position. We took advantage of this unique site to cleave P1A by *Sac*II, and, by the same procedure as that used for construction of P1A, isolated the mutant AS. To construct the mutants of the PS series, pSV1 was linearized at the unique *Eco*RI site, and treated with *Bal*31 nuclease (BRL)^{13,42} to remove up to 200 base pairs from the extremities thus generated. The DNA was then treated with *Sal*I and ligated to an *Eco*RI-*Sal*I fragment from pBR322. Selection of tetracycline-resistant bacteria allowed the isolation of mutants bearing deletions on the SV40 side of the *Eco*RI site only. The construction scheme of HS mutants has been reported in detail previously¹³.

Goldberg-Hogness or the TATA box, has been regarded as a promoter sequence analogous to the Pribnow box sequence of prokaryotic organisms. Nevertheless, genes (such as those coding for papovavirus late function and adenovirus-2 72,000 molecular weight (72K) DNA binding proteins)⁴⁻⁸ lack the TATA box, so that its proposed function remains conjectural.

Using *in vitro* transcription systems that allow RNA polymerase B to transcribe cloned DNA templates^{9,10}, the TATA

box has been shown to be involved in promoter function *in vitro*^{2,11,12}, but *in vivo* studies suggest that these results should be extrapolated with caution. Thus for SV40 early genes, we and others¹³⁻¹⁵ have shown that removal of all sequences upstream from the cap site, but not the mere removal of the TATA box¹³, abolishes expression. Similarly, the TATA box is not essential for expression of the sea urchin histone H2A gene injected into *Xenopus* oocytes although its absence leads to the use of several new cap sites¹⁶.

Fig. 2 Sequence of the SV40 deletion mutants. The sequence corresponds to the DNA non-coding strand of the early promoter region which was cloned in pSV1, and is identical to that of wild-type SV40 strain 776^{29,41,43}, except for an 8-base pair deletion (positions 116-108, see text). The numbering system is as in Fig. 1. The 72-base pair repeats are shown in two dashed boxes, the TATA box in a solid box. Horizontal lines above the sequence delimit the five G+C-rich blocks (see text). a, Sequence of mutants in the HS group, which all share a common end point at position 5,162 indicated by a vertical line and a large arrow. The other deletion end points are shown by thinner arrows (and dotted lines for those which have been sequenced). Deletions present in mutants P1A and AS around the *Bgl*I site are indicated by double pointed arrows. b, Sequence of the mutants in the PS series. All deletions originate at the *Eco*RI site (Fig. 1) and extend to the point defined by thin arrows. The extent of the deletions was established for all mutants by DNA sequencing except for mutants HS102, HS40, PS2 and PS359, where the size (± 8 base pairs) of the deletions were estimated by gel electrophoresis after *Hind*III digestion. Sequences were obtained by the technique of Maxam and Gilbert²¹ after 5'-end labelling at the *Hind*III site 2 (Fig. 1) and secondary cleavage with *Eco*RI (P1A, AS and HS mutants) or by end labelling at the *Hind*III site 1 and secondary cleavage with *Bgl*I (PS mutants). The exact sequence of some of the mutants is shown in Fig. 6a.

Fig. 3 Mapping of the 5' ends of SV40 early mRNAs present in several rat (3T3) fibroblast transformed cell lines (see text). Cytoplasmic RNA was extracted from such cloned cell lines by NP40 lysis and phenol-chloroform extraction, and poly(A)⁺ RNA selected by oligo(dT)-cellulose chromatography. *a*, Mapping by reverse transcriptase primer extension. A *Hinf*I-*Hind*III primer (positions 5,070–5,107, Fig. 1) ³²P-5'-end labelled at its *Hinf*I extremity, was purified by electrophoresis on an 8% acrylamide/7 M urea gel. It was then denatured in H₂O for 2 min at 100 °C, quick-frozen in liquid nitrogen and thawed in 50 mM Tris-HCl pH 8, 10 mM MgCl₂ and 140 mM KCl in the presence of poly(A)⁺ RNA (2–5 µg). After 5 min at 65 °C dATP, dGTP, dCTP and TTP (0.5 mM each) and β-mercaptoethanol (20 mM) were added and the samples were incubated for 2 h at 37 °C in the presence of 4 units of reverse transcriptase. Samples were diluted to 0.1 M NaOH, 3 mM EDTA and 5 M urea, and aliquots electrophoresed on 8% acrylamide/7 M urea thin gels⁴⁴. RNAs were from cell lines transformed with wild-type SV40 or recombinant mutants as indicated. 'M' is a sequencing ladder obtained by Maxam and Gilbert²¹ cleavage (A + C) of a *Hinf*I-*Eco*RI fragment of pSV1 (positions 5,070–282) end labelled at its *Hinf*I extremity. The positions of the '5'-end bands' are given in Fig. 6 legend. Aside from the major cap sites, a few other bands can be seen (see lanes 2 and 3, for example) that probably correspond to reverse transcriptase 'false stops' as they are not obtained by S₁ mapping. *b*, S₁ nuclease mapping of the 5' ends of the RNAs (as indicated). The coding strand of SV40 fragment *Eco*RII G (positions 5,027–99) was 5'-end labelled and purified by polyacrylamide gel electrophoresis as described in ref. 21. After denaturation for 5 min at 85 °C, the probe was hybridized to RNAs (1–3 µg) from transformed cell lines for 12 h at 42 °C in 50% formamide, 10 mM PIPES pH 6.4 and 0.4 M NaCl. Digestion with S₁ nuclease (Miles) and subsequent steps were as in ref. 45. S₁-resistant hybrids were analysed by electrophoresis on an 8% acrylamide/7 M urea thin gel. M_A and M_B: sequencing ladder from an *Eco*RII/*Bgl*I (5,027–5,177) cleaved by the technique of Maxam and Gilbert [M_A, A + C; M_B, C + T]. Arrows 1–7 indicate the common bands found with RNAs from all lines transformed with HS mutants lacking the TATA box (positions 5,134, 5,127, 5,124, 5,117, 5,112, 5,103 and 5,085). The 'O' bracket shows the area where initiation varies from one mutant to the next (see text). The 'UP' band corresponds to RNA species initiating upstream from the position of the deletion (see text). *c*, Same as *b*, where a longer exposure reveals the presence of bands 1–4 and 7 obtained with HS4 RNA (arrowheads), but not with SV40 RNA. Numbering of lanes as in *b*.

The SV40 early gene products (small t and large T antigens), which initiate viral DNA replication in permissive monkey cells, stimulate various host cell functions and transform non-permissive systems (see ref. 17 for review), are coded for by different mRNAs derived from a common primary transcript by different splicing patterns, and have identical 5' and 3' ends^{18,19}. The major 5' ends of SV40 early mRNAs map at a few closely positioned cap sites, around positions 5,165 and 5,171 on the SV40 sequence (refs 19, 20; see also Figs 1, 6). Upstream from the cap sites are located, successively, a 27-base pair palindrome, a TATA box (TATTTAT, at position -21 to -27 base pairs from the most upstream of the cap sites), a nearly perfect triple tandem of a highly G + C-rich 21-base pair sequence, and a perfect tandem repeat of a 72-base pair sequence (-116 to -188 and -189 to -261 base pairs from the cap site) (see Figs 1, 2).

We have previously reported¹³ that T-antigen synthesis can be induced by mutant plasmids containing an SV40 early region from which the TATA box has been deleted. We have now analysed the 5' ends of RNA species synthesized on such mutant templates, and conclude that initiation at the wild-type cap sites requires the presence of the TATA box. In the absence of the TATA box, transcription begins at several new sites. Moreover, we find that the expression of the SV40 early genes is severely impaired by deletions in the region of the 72-base pair repeats, which accordingly seems to have a crucial and independent role in initiation of transcription.

Deletion mutants of SV40

The mutants described here were derived from the plasmid pSV1¹³, which contains the entire early gene segment (as the large *Bam*HI-*Hpa*II fragment of SV40), cloned into the *Eco*RI site of pBR322. From this, we have constructed three groups of deletion mutants (see Fig. 1 legend). After preliminary screening by restriction enzyme digestion, the extent of the deletions was established (in most cases, see Fig. 2) by DNA sequencing²¹.

The first group of mutants is represented by plasmids P1A and AS, with deletions between the TATA box and the cap sites of 3 and 9 base pairs, respectively (Figs 1, 2a). Figure 1 depicts schematically the position of the deletions in the second (PS) and third (HS) groups of mutants. Deletions in the PS series share an end point at the *Eco*RI site at the boundary of the SV40 and pBR322 sequences in pSV1, and extend progressively further downstream towards the early genes. The same pBR322 sequences are always present at the boundary, which greatly facilitates screening and eliminates one source of variability in

studying the effect of deletions in the SV40 sequence. Deletions in the HS mutants all extend upstream from position 5,162 (ref. 13), and thus delete the cap site and usually the TATA box, which is nevertheless left intact in HS0, HS3 and HS4 (Figs 2, 6). On mutant sequences, all have an 8-base pair deletion at the junction between the two 72-base pair repeated sequences (positions 116–108), apparently because the SV40 fragment cloned in pSV1 is derived from a variant of SV40 strain 776 (Fig. 2).

In vivo expression of SV40 early genes in mutant plasmids

Our demonstration that deletion of all sequences upstream from the cap site abolishes SV40 early gene expression¹³, shows that some sequence element between the TATA box and *Hpa*II site

Table 1 *In vivo* expression of the deletion mutants

Short-term		Long-term	
Plasmids	T antigen-positive cells per 2 × 10 ⁴ cells	Plasmids	Foci per plate
pSV1	105	pSV1	132
AS	72	HS4	115
HS4	91	HS2	118
HS2	78	HS105	72
HS12	17	HS102*	17
HS66	15	HS38*	21
HS40	6	HS111*	7
HS38	8	HS240*	1
HS111	0	PS214*	15
PS224	12	PS366*	13
PS366	0		

Short-term experiments: Plasmid DNA (0.2 µg) was diluted in 200 µl of Dulbecco's modified Eagle's medium (DMEM), followed by the addition of 200 µl of a 1 mg ml⁻¹ solution of DEAE-dextran (Sigma) in DMEM. Sub-confluent CV1 monkey cells, grown in 60-mm Petri dishes¹³, were washed twice with phosphate-buffered saline (PBS); the DNA solution was added and, after incubation for 15 min at room temperature, the cells were washed once with PBS and once with complete medium. After addition of medium, they were incubated at 37 °C. Indirect immunofluorescence was performed 40 h after transfection, essentially as described in ref. 39, 10 µl of the antibodies¹³ being spotted directly on to the cell monolayer fixed to the dish with acetone/methanol (3:7 v/v). T antigen-positive cells were counted under a fluorescence microscope. Long-term experiments: Transformation of non-permissive cells. Fisher rat fibroblasts (FR3T3), grown in 100-mm Petri dishes¹³, were transfected with 1 µg of plasmid DNA, as described in ref. 40. Dense foci overgrowing the cell monolayer were counted 3 weeks after transfection. Asterisks indicate that foci were counted 4 weeks after transfection and that they were checked by immunofluorescence to eliminate foci due to spontaneous transformation (5–10 per dish). All the data shown in this table represent results obtained in typical experiments. The absolute figures are only indicative, however, as they may vary by as much as 50% between experiments.

Fig. 4 S_1 nuclease mapping showing the full extent of the 5' ends of RNAs from cells transformed with HS mutants lacking the TATA box. The experimental protocol is the same as that described in Fig. 3b legend (4 μ g of poly(A)⁺ RNA for SV40 and HS2; HS12, 8 μ g; HS66, 38 μ g; HS111, 15 μ g); the probe used was the coding strand of the *TaqI*-*BglI* fragment of SV40 (positions 4,675–5,180), 5'-labelled at its *TaqI* extremity. S_1 -resistant hybrids were analysed on a 5% acrylamide/7 M urea thin gel. M_A : 5'-end labelled fragments from a *HpaII* digest of pBR322 (sizes from top in base pairs: 527, 404, 309, 242, 238, 217, 201, 190, 180). M_B : 5'-end labelled fragments from a *HinfI* digest of SV40. The origin of the RNAs is indicated at the top of the lanes. The resolution on a 5% polyacrylamide gel is not sufficient to separate the band mapping at the position of the deletion (UP) from those immediately below (region O) (see Fig. 3b). Similarly, bands 1–6 are poorly separated. Bands 7–11 correspond to 5' ends of RNA species mapping at positions (± 10 base pairs) 5,085, 5,023, 4,985, 4,962 and 4,897, respectively. (Only the major bands 1–11 are numbered, but a large number of more minor cap sites are also present, for example, HS2 RNA, where at least 10 such bands can be seen between bands 7 and 11 on the original autoradiogram.)

(position 282, Fig. 1) is essential for transcription. We have therefore analysed the *in vivo* expression of the early genes of HS and PS mutants (Fig. 2).

Two approaches were followed (Table 1). In short-term experiments, gene expression was detected by T antigen-specific immunofluorescence 40 h after transfection of permissive CV1 monkey cells with the recombinant plasmids. In long-term experiments, we assayed the ability of the deletion mutants to induce morphological transformation of rat 3T3 fibroblast cells (tested by the appearance of T antigen-positive dense foci overgrowing the cell monolayer).

In the short-term experiments, HS mutants (Fig. 2a) up to and including HS38 induced a T antigen-positive immunofluorescence pattern, with an intensity unaffected by deletion of the TATA box (HS2 and 6), but inversely proportional to the length of the deletions (HS66, 40 and 38). On the other hand, the responses with HS16, 111, 240, 232 and 109 were not unambiguously positive. With the sequence of PS mutants (Fig. 2b), gene expression was allowed down to those in PS224 and 214, but with these two mutants the fluorescence intensity was lower than that obtained with the wild-type recombinant pSV1; in contrast, PS366 and 359 gave negative results. We have also assayed by blot hybridization²² for SV40-specific early RNAs in

poly(A)⁺ RNA extracted from CV1 cells 40 h after transfection with various plasmids, and have found none in cells when the mutants were negative by immunofluorescence (not shown). The sensitivity of such experiments is low, however, and it is possible that a low level of transcription (<10% of that obtained with pSV1) occurs with mutants which do not induce T-antigen immunofluorescence.

These experiments therefore show that the region of the 72-base pair repeats (Figs 1, 2) is necessary for efficient expression of the early genes. However, morphological transformation studies were somewhat more ambiguous. As expected, rat 3T3 cells were transformed by HS mutants up to HS38, but the efficiency of transcription was decreased with mutants such as HS40 or HS38. Using RNA blot analysis, we have quantitated the amount of early RNAs present in lines of such transformants. Like Gluzman *et al.*¹⁴, we found that the levels of these RNAs were higher in cells transformed with mutants bearing deletions downstream from the TATA box than in cells transformed with pSV1 (although the increase varied from 2- to 10-fold with different lines; our unpublished results). These levels were not affected by further deletion of the TATA box, but decreased with HS mutants bearing longer deletions (not shown). However, in contrast to the short-term experiments, T antigen-positive transformed foci were induced by HS111, HS240 and PS366, although in reduced numbers (5–10 foci per μ g of DNA per 10^6 cells compared with 50–100 for pSV1 and short deletion HS mutants) and more slowly (25–30 days compared with 10–14 days).

Transcription initiation on mutants retaining the TATA box

Using both S_1 nuclease mapping with single-stranded ³²P-5'-end-labelled probes²³ and reverse transcriptase primer extension mapping¹⁹ (see Figs 1, 3), we have investigated the 5' ends of SV40-specific RNAs present in cloned rat fibroblast cell lines transformed by HS mutants. We believe both types of experiments to be necessary because of the risk of artefacts, particularly with the primer extension method (see Fig. 3 legend). We have assigned (Fig. 6a) the major 5' ends of SV40 early mRNAs to positions 5,172, 5,171 and 5,165 (both in RNA isolated 32 h after infection by wild-type virus²⁴ and in lines transformed by wild-type SV40 or pSV1; Fig. 3a and unpublished results). However, because results obtained by the two methods often differ by 1 or 2 base pairs (compare, for instance, Fig. 3a with Fig. 5a of the accompanying paper²⁴), and because of discrepancies in previous reports (refs 18–20 and Y. Groner, personal communication), we do not consider these assignments definitive.

Figure 3a and b give the 5'-end analysis of RNAs transcribed from deletion mutants retaining the TATA box. The 3-base pair deletion in P1A results in initiation mainly at position 5,165, with almost complete disappearance of the two wild-type 5' ends upstream at positions 5,172 and 5,171. On mutants with longer deletions downstream from the TATA box (AS, HS0, HS3, HS4), transcription begins further down, with the 5' ends always mapping at about the same distance from the TATA box (27–34 base pairs from the first T, Fig. 6a). This shift seems to be independent of the presence (P1A, AS) or absence (HS0, HS3, HS4) of the wild-type cap sites. In those mutants which do conserve the TATA box, there are very few cap sites.

Transcription initiation on mutants lacking the TATA box

The clearest consequence of the removal of the TATA box is the generation of multiple cap sites, as shown for mutants HS2 and HS105 (Fig. 3b). Identical bands (arrows 1–7 in Fig. 3b) were observed with all the mutants lacking the TATA box, but with varying intensities (see below). Between band 1 and that corresponding to the end point common to all deletions (arrowhead 'UP'), patterns varied between mutants (region O in Fig. 3b) although some cap sites were common to several mutants (Fig.

5). We investigated this multiplicity further by S_1 mapping using a single-stranded probe end labelled at the *TaqI* site (position 4,675, Fig. 1), and found that in the absence of the TATA box, initiation occurs up to 270 base pairs downstream from the normal 5' ends (Fig. 4, band 11). These cap sites are not usually seen with wild-type SV40 RNA (Fig. 4), but it is just possible to detect them using very large amounts of such RNA (not shown). As the probes used in the experiments shown in Figs 3b and 4 were derived from wild-type SV40 DNA, RNA species from HS mutants and with their 5' ends mapping upstream from the position of the deletion lead to the appearance of a band ('UP' in Figs 3b, 4) at that position. With mutants such as HS2 and 105 these RNAs are relative minor, with most of the initiation occurring downstream.

Figure 4 shows the effect of increasingly long HS deletions including the TATA box and sequences upstream. Although identical bands are found with mutants HS2, 12, 66 and 38, the ratio of the intensity of these bands varies, the lower bands becoming more prominent with increasing deletion. For example, whereas bands 1–6 are most important in HS2 RNA, they are barely detectable in HS38 RNA, while the relative intensities of the lower bands 8–11 increase (see Fig. 6b for quantitation). It thus appears (similar results were obtained reproducibly in several experiments) that, although identical cap sites are shared by various HS mutants, their use is influenced by their distance from sequences found upstream from the HS38 deletion end point.

HS111 RNA shows a very different pattern, with the disappearance of the lower bands 8–11 and a relative reappearance of the higher bands 1–7; most of the RNA initiates upstream from the position of the deletion ('UP' in Fig. 4). This 'UP' band is also intense in HS38 RNA. We investigated the cap sites located upstream from the position of the deletion by mapping the 5'

ends of RNAs from cell lines transformed with HS2, 105, 66 (not shown), 38 and 111 (Fig. 5) with probes derived from corresponding mutant DNAs. Autoradiograms from experiments such as those shown in Figs 3, 4 and 5, were scanned and the results are summarized in Fig. 6b. With HS2, 105 and 66 RNAs the 'upstream' RNA species are heterogeneous and quite minor, their 5' ends mapping immediately upstream from the position of the deletion. For HS111, however, they are of much higher relative abundance, and are represented by a set of bands (Fig. 5) which correspond to initiation within the 72-base pair repeat 1 (Figs 1, 2). This set of bands is also observed, but at much lower relative abundance (Fig. 6b) and with a somewhat different distribution of intensities (Fig. 5), with HS38 RNA, where most of the upstream RNAs map far into the late region (X on Figs 5, 6b). Although very faint bands, perhaps corresponding to the set observed with HS111 RNA, were detected in HS2 RNA, no other HS RNAs showed any species equivalent to the 'X' bands seen with HS38 RNA.

Although we have assumed throughout that the bands obtained in S_1 mapping experiments correspond to 5' ends of the RNAs it is possible that these bands correspond to the position of acceptor sites in RNA splicing. However, multiple splicing events would then appear suddenly after the small deletion from HS4 to HS2, and the relative use of acceptor sites would be further modified by increasing deletions. Splicing can be ruled out for RNAs transcribed on mutants which conserve the TATA box and for bands 1–4 in the cases where this sequence is absent, as these 5' ends are also found by reverse transcriptase primer extension mapping (Fig. 3a and data not shown). Another interpretation is that as the RNAs studied are extracted from transformed cell lines, some of the bands seen in the S_1 nuclease mapping experiments could have been due to sequence rearrangements or integration behind cellular promoters during transformation. As such events are unlikely to occur similarly in a number of cell lines transformed by different mutants, this objection is probably not valid for bands 1–11 which are found with all mutants, nor for the set of bands found in both HS111 and HS38 RNAs, but may explain the bands found only with HS38 RNA, in region X (Fig. 5).

Function of the TATA box region

Our studies on the above mutants, in agreement with recent reports (refs 14, 16 and Y. Gluzman, personal communication), clearly show that the TATA box has a key role in fixing the start sites within a narrow area (we assume that the RNA 5' ends correspond to transcription start sites). Deletions in such mutants shift these sites so that initiation always occurs 27–34 base pairs downstream from the first T of the TATTTAT sequence (the slight variations in this distance and in the number of start sites presumably reflect the influence of the actual DNA sequence around the cap site^{2,24}).

When the TATA box is absent, new cap sites appear, but no TATA-like sequences are found upstream from the cap sites (except possibly for band 10, Fig. 4). We hypothesize that sequence elements, not obviously related to the canonical TATA box sequence, can functionally substitute for the TATA box to dictate the position of RNA 5' ends and might also direct initiation 30 base pairs downstream, as the first 5' end common to all TATA-minus mutants (band 1 in Figs 3b, 6) maps 30 base pairs downstream from the position of the deletion. In the wild-type situation, these substitute elements would be masked by the TATA box, which might be recognized more readily by RNA polymerase and/or other factors involved in transcription initiation. A functionally similar element might be operative in polyoma late genes and the gene for the adenovirus 72K DNA binding protein, which exhibit a microheterogeneity of mRNA 5' ends over a narrow area, but do not have TATA-like sequences at the expected position^{4,6}.

The key sequences performing the 'fixing' function for initiation at the major early cap sites must be present in HS4, but absent from HS2 (Figs 2, 3). Although the TATA box is included in this region, other sequences could influence its

Fig. 5 S_1 nuclease mapping of 5' ends of RNA species that initiate upstream from the position of the deletion, in RNA extracted from cell lines transformed with HS38 and HS111. The probes used were the *HinfI*–*EcoRI* fragments (5,070–282) derived from HS38 and HS111 DNAs, and 5'-end labelled at their *HinfI* extremity. The specific activities of the probes were different, as were the amounts of RNA used (HS38, 2 μ g; HS111, 3.5 μ g). M_{38} and H_{111} are sequence ladders obtained by (A + C) cleavage of the probes. HS38 and HS111: the probes were hybridized to RNA from corresponding cell lines, digested with S_1 nuclease and electrophoresed as described in Fig. 3 legend. The markers and experimental tracks are from different exposures of the same gel. Positions are those on the wild-type SV40 sequence (numbering as in Figs 1 and 2) and arrowheads indicate the position of the deletion (5,162). 'O' brackets the region 0 (defined in Fig. 3 legend) between the position of the deletion and band 1 at position 5,135. Arrows on the right indicate the bands obtained with HS111 RNA (positions 117, 119, 120, 135, 144, 151 and 153). These bands are observed at identical positions with HS38 RNA (arrows

on the left of the figure; the bands are faint but were clearly visible on the original autoradiogram). Bands obtained with HS38 RNA only are bracketed and labelled X. In both HS38 and HS111, a band can be seen which corresponds to full-length unreacted probe (dotted arrow 'P'). That this band is not due (at least for HS111) to RNA species initiating further upstream was established by an experiment in which the *HinfI* end-labelled probe extended for 600 base pairs into the pBR322 sequences (Fig. 1). No additional bands were observed in this experiment (not shown).

Fig. 6 Location of the 5' ends of early RNAs present in lines transformed by deletion mutants of pSV1. *a*, Position of cap sites on mutants that retain the TATA box. The sequences of the mutants are shown, aligned on the 'TATTTAT' sequence (boxed). Arrowheads indicate the position of the deletion; the few extra nucleotides which originate from the construction of HS mutants are underlined¹³. Symbols for cap sites are as in Fig. 1. Their position was derived from the results shown in Fig. 3a and other unpublished S₁ and reverse transcriptase mapping experiments and map at the following position: P1A, 5,165; AS, 5,160 and 5,161; HS0, 5,154 and 5,155; HS3, 5,149, 5,151 and 5,152; HS4, 5,145 and 5,146. As discussed in the text these positions are only tentative (± 2 base pairs). Only the major cap sites are represented, yet, as can be seen in Fig. 3a, minor cap sites exist; for example, the HS0 5' ends are also present in AS, HS3 and HS4 RNAs. *b*, Position and relative contribution of the RNA 5' ends found with HS mutants lacking the TATA box. Symbols are the same as in Fig. 1, as is the numbering system. The common deletion end point is shown by a vertical dashed line. Cap sites are shown by arrowheads and are numbered (on the second line only) as defined in Figs 3b and 4. The cap sites that vary from one mutant to the next ('region O', and the region immediately upstream from the deletion end point) are not shown individually, nor the closely spaced cap sites of mutants HS38 and HS111 that map within the 72-base pair repeat I. The brackets and the percentages above the cap sites indicate the proportion of RNA species initiating in that region, as deduced from scans of autoradiograms from several S₁ mapping experiments with wild-type probes end labelled at the *Hinf*I, *Eco*RII, *Taq*I sites (Fig. 1) or experiments with mutant probes as shown in Fig. 5. Percentages for HS38 are calculated omitting the bands in region X, which represent 45% of HS38 RNA 5' ends.

function. Indeed, bands 1-4 and 7, characteristic of mutants lacking the TATA box, can be detected faintly in HS4 RNA (Fig. 3c), but are absent in RNA transcribed on the wild-type gene or on HS mutants with shorter deletions. It is as if the TATA box in HS4 were beginning to relinquish its dominance, an interpretation supported by the relative inefficiency of HS4 DNA (see accompanying article²⁴) in directing accurate initiation of transcription *in vitro* to a site about 30 base pairs downstream.

The deletion of the TATA box does not seem to affect early gene expression quantitatively (Table 1). The possibility that down mutations would be masked if they eliminated T-antigen binding and repression²⁵⁻²⁸ probably does not apply as the T-antigen binding site II is already absent from HS4^{26,28}.

Far upstream sequences are required for transcription initiation

The most important element for SV40 early gene expression is clearly not the TATA box, for mutant PS366, which has a deletion far upstream from the TATA box, transforms rat cells very inefficiently and does not induce detectable T antigen in short-term experiments, while the expression of various mutants in monkey cells indicates that, at least in this system, the essential elements lie in the region of the 72-base pair repeats. Results obtained with mutants HS38 and PS214 suggest that deletion of one of these two repeats still allows transcription, in keeping with studies of mutants or variants of SV40 which possess only one copy of this repeat (see ref. 29 for refs). Although the lower efficiency of mutants HS66 or HS38 (Table 1) might suggest the involvement of other sequences, such as the G+C-rich 21-base pair repeats, this could also be accounted for by the position of the 5' ends of RNAs synthesized on such templates, downstream from the normal T-antigen initiation codon. The results obtained with the PS214 and PS224 are in

contrast with the aforementioned mutants and variants of SV40, whose early gene expression appears normal. This might indicate the involvement of sequences even further upstream than the 72-base pair repeats, or that pBR322 sequences have some inhibitory effect when brought closer to the gene.

Increasingly long deletions (HS2, HS12, HS66, HS38) affect the relative intensities of the common bands 1-11 with a pattern (Fig. 6b), suggesting that initiation takes place predominantly at a fixed distance (broadly speaking 150-200 base pairs) from sequences located upstream from the deletion endpoint of HS38. This pattern is drastically altered with mutant HS111, which bears a deletion only 12 base pairs longer than that of HS38. In addition, HS111 does not induce detectable T-antigen synthesis in CV1 cells, whereas HS38 does. There are five sets of highly G+C-rich 20-base pair sequences in the early SV40 promoter region (Figs 1, 2). The G+C-rich sequence of the 72-base pair repeat II is almost eliminated in HS111, but essentially left intact in HS38. We suggest that this sequence is involved in controlling the pattern of initiation in mutants HS2 to HS38; HS111 transcription would then be under the control of the same G+C-rich sequence of repeat I. If this is the case, the effect of the G+C-rich sequences must be complex: predominant initiation occurs in HS111 only 10-60 base pairs downstream from the G+C-rich sequence of repeat I, whereas it occurs ~200 base pairs downstream from its counterpart in repeat II, when this is present (HS2 to HS38). The relatively constant amount of RNA species initiating in region 0 or immediately upstream (Fig. 6b) is also puzzling.

We have observed that mutants which do not support early gene expression in CV1 cells, such as HS111, HS240 and PS366, can, albeit inefficiently, nevertheless transform rat fibroblast cells. As these transformants could reflect a low level of transcription, not detected in short-term experiments because of a lower sensitivity, we are now investigating the extent of sequences necessary for such transformation (bearing in mind

the possibility that template rearrangements could be involved; see above).

We do not know how sequences lying more than 150 base pairs from the cap sites exert their influence. The structure of SV40 chromatin is known to be in a very 'open' conformation in the early promoter region³⁰⁻³⁴. Moreover, the chromatin structure around the 5' end of several 'active' cellular genes is extremely sensitive to DNase I (refs 35, 36 and M. Bellard, personal communication). It is possible that the upstream sequences somehow induce this peculiar chromatin structure, which in turn would allow the RNA polymerase to interact, directly or indirectly, with the TATA box. Alternatively (or concomitantly), these sequences could be part of the RNA polymerase binding site²⁴, or interact with proteins exerting a positive control over transcription.

Can the organization found for the SV40 early promoter region be generalized to other systems? There is no clear homology between the SV40 sequence upstream from the TATA box and regions upstream from the 5' end of other genes. However, both polyoma early genes (R. Kamen, personal communication) and the sea urchin H2A gene (R. Grosschedl and M. Birnstiel, personal communication) have sequences lying upstream from the TATA box, in a position roughly analogous to that of the 72-base pair repeats in SV40, which are essential

for gene expression. Thus, it is possible that sequence elements will be found in other genes that have an analogous role to that of the 72-base pair repeat region in SV40.

In conclusion, if a eukaryotic promoter region is defined as being composed of all the sequences necessary for proper initiation of transcription *in vivo*, the SV40 early promoter has (at least) three components: the TATA box and cap site regions which accurately position initiation of transcription, and the sequences in the region of the 72-base pair repeats which allow, within the area they potentiate, initiation of transcription and TATA box function. The requirement for the far upstream sequences, which have no counterpart in prokaryotes, may reflect the importance of chromatin structure in the control of gene expression in eukaryotes^{37,38}.

We thank Drs J. Beard and R. Wilsnack for gifts of reverse transcriptase and antiserum, Drs R. Breathnach, K. O'Hare and D. Mathis for helpful advice, K. Dott, J. M. Garnier, M. C. Gesnel, L. Thia-Toong and Dominique Schmitt for technical assistance, and B. Boulay for photography. The SV40 early region TATA box is required for accurate *in vitro* initiation of transcription

Diane J. Mathis* & Pierre Chambon

Laboratoire de Génétique Moléculaire des Eucaryotes du CNRS, Unité 184 de Biologie Moléculaire et de Génie Génétique de l'INSERM, Institut de Chimie Biologique, Faculté de Médecine, 67085 Strasbourg, France

The SV40 early region TATA box functions in vitro to fix initiation of transcription within a narrow region identical to that in vivo. In the absence of the TATA box region initiation occurs at multiple specific sites, as in vivo. However, certain sequences far upstream, crucial for efficient in vivo expression, are not essential in vitro.

THE development of cell-free systems allowing selective and accurate initiation of transcription by RNA polymerase B (II)^{1,2} has given a new impetus to studies of the control of eukaryotic gene expression. Viral¹⁻³ and cellular^{3,4} genes have been transcribed using either a whole-cell² or cytoplasmic (S100)¹ extract

from HeLa or KB cells, and have generally shown close correspondence between the *in vitro* transcription start site for a given gene and its *in vivo* cap site (the nucleotide coding for the 5'-end of the mature mRNA).

This apparent fidelity has allowed the use of a HeLa cell-free system to delineate the DNA sequences required for specific RNA polymerase B initiation. Corden and co-workers⁵ have reported that the DNA segment 12-32 nucleotides upstream

* Present address: Stanford University School of Medicine, Department of Medical Microbiology, Stanford, California 95304, USA.

Fig. 1 Maps of the cloned 850-base pair SV40 *HpaII*-*TaqI* fragment. *a*, Relevant restriction enzyme sites. The SV40 sequence has been numbered according to the system proposed in ref. 12. Note that for our SV40 strain the *HpaII*-*TaqI* fragment lacks 8 base pairs which include an *EcoRII* site (nucleotides 108–116)¹³. The arrowed lines indicate the approximate size of expected run-off fragments (see Fig. 2). *b*, Location of mutant deletions and delineation of important functional elements. A more precise description of the mutants can be found in ref. 13. The major late cap site is that mapped by Ghosh and co-workers¹⁴; the major early cap sites were assigned according to refs 20 and 21, the accompanying paper¹³ and data within this paper. +1 corresponds to the early cap site at position 5,172. The stippled boxes represent the 72-base pair repeats. *c*, Sequence around the TATA box and wild-type cap sites²⁷. The arrows indicate the deletion end points for mutants HS2 and HS4. The boxed nucleotides are those included in a 27-base hairpin around the *Bgl*I site.

from the cap site of the adenovirus 2 (Ad-2) major late transcription unit suffices to promote specific initiation *in vitro*; similar results were obtained with a DNA segment 10–44 base pairs upstream from the conalbumin gene cap site⁵. These segments share the sequence 5'-CTATAAAAGGGG-3', which includes the TATA or 'Goldberg-Hogness' box (underlined) thought to be involved in promoting specific initiation, because it is conserved before the 5' end of most RNA polymerase B-transcribed genes^{6–9}. Moreover, specific RNA polymerase B initiation is essentially abolished on mutants with deletions involving the TATA sequence⁵, and when the conalbumin gene TATAAAA sequence is mutated to TAGAAAA, specific *in vitro* transcription is drastically reduced¹⁰. The conclusion, then, is that the TATA box has a fundamental role in promoting specific initiation by RNA polymerase B, at least *in vitro* using naked DNA templates and HeLa cell-free extracts.

Two studies cast doubt on whether the TATA box has an identical role *in vivo*. Deletion of the TATA box does not abolish transcription of the sea urchin H2A histone gene in *Xenopus laevis* oocytes¹¹ nor that of the SV40 early region in mammalian cells^{12,13}, but instead generates a new set of start sites. One might argue, of course, that these genes have atypical promoters—the histone genes are preceded by extensive A+T-rich ‘spacer’ regions and the SV40 early region TATA box is embedded in a highly A+T-rich region (5'-TAATTTTTTTT-TATTTAT-3'). Such sequence organizations are not typical of known RNA polymerase B-transcribed genes⁹, and the H2A genes and SV40 early region TATA boxes may not have retained their usual function(s). Alternatively, RNA polymerase B may not see the TATA box in the same context *in vivo* as *in vitro*.

It seems necessary, then, to assess the fidelity of the *in vitro* transcription systems at another level. Do mutations within a given DNA segment affect its *in vitro* and *in vivo* transcription identically? Here we compare the SV40 early region transcripts generated in a HeLa S100 extract with those detected *in vivo* in mammalian cells. We first establish that *in vitro* RNA polymerase B initiates transcription accurately on the early gene region, then compare the effects of various deletions in the promoter region on initiation *in vivo* and *in vitro*. The construction of these mutants and a detailed study of their *in vivo* expression are described in the accompanying article¹³.

RNA polymerase B can initiate accurately on the SV40 early region *in vitro*

Using a 'run-off' assay¹ we first determined whether RNA polymerase B could initiate accurately *in vitro* on the SV40 early region. A cloned fragment containing the SV40 early sequences *HpaII-TaqI* (see Fig. 1 and Fig. 2 legend) was purified and incubated with RNA polymerase B and ³²P-GTP in the presence of a HeLa S100 extract. The newly synthesized RNA was isolated, electrophoresed on a denaturing gel and detected by autoradiography. If initiation of transcription *in vitro* occurred at the major early start sites used *in vivo*, a 'run-off' RNA fragment about 500 base pairs long would be expected (Fig. 1; see below and ref. 13 for details of the assignment of major *in vivo* early cap sites). Transcripts initiating at the major *in vivo* late cap site¹⁴ would appear as short fragments of about 25 base pairs and should therefore not interfere with the assay. Two prominent 'run-off' bands were observed (Fig. 2, lane 2), one (*a*) about 500 base pairs long and possibly due to initiation at the major *in vivo* early start sites, the other (*b*) resulting from initiation about 80 base pairs downstream. We determined that

Fig. 2 Run-off analysis of RNA transcribed *in vitro* from wild-type SV40 early promoter. The 850-base pair *HpaII*-*TaqI* fragment from SV40 was inserted into the *EcoRI* site of pBR322 by blunt-end ligation after DNA polymerase I repair. The SV40 sequences could be excised from the resulting plasmid, pSV3, by *EcoRI* digestion, and were subsequently purified by sucrose gradient centrifugation. The purified fragment was incubated in a HeLa cell-free system and the run-off transcripts analysed as previously described^{3,5}, except for the following modifications. (1) The protocol for preparing S100 extract omitted the hypotonic cell washes but included a 30-min incubation of cells at 4°C in hypotonic buffer. Also, the cell homogenate was incubated at 0°C for 30–60 min after being rendered isotonic. (2) The NTP concentration during the RNA synthesis reaction was 200 µM ATP and UTP and 10 µM GTP and CTP. Lane 2, run-off transcripts from the 850-base pair *EcoRI* fragment from pSV3 (containing the Sv40 *HpaII*-*TaqI* sequence); lane 3, transcripts from the same *EcoRI* fragment subsequently cut by *Sau* 3A1; lane 4, 1 µg ml⁻¹ α-amanitin was included in the standard assay of transcripts from the pSV3 *EcoRI* fragment; lane 5, exogenous RNA polymerase B was omitted from the standard assay for transcripts from the pSV3 *EcoRI* fragment; lane 6, no DNA was added to the standard assay; lane 7, transcripts of the pSV3 *EcoRI* fragment generated in the absence of S100 extract; lane 9, lane 7 exposed for 1/15th the time; lanes 1 and 8, 5'-end-labelled *HpaII* digests of pBR322. Sizes for these sequenced marker fragments are indicated on the left.

these bands were due to synthesis from the early strand by using an *HpaII*-*Sau* 3AI fragment (Fig. 1a) as template in the *in vitro* system. We found that, as expected for transcripts synthesized from the early strand using this template, the two predominant RNA bands (a and b) obtained were about 30 base pairs shorter (Fig. 2, lane 3). That both bands represented transcription by RNA polymerase B was inferred from their absence when $1 \mu\text{g ml}^{-1}$ α -amanitin was included in the assay (Fig. 2, lane 4). When RNA polymerase B was omitted, the bands were present but at reduced intensity (Fig. 2, lane 5), indicating that active polymerase B exists in the S100 extract. No bands were detected when DNA was omitted (Fig. 2, lane 6), and in the absence of S100 extract the entire gel lane was blackened. On briefer exposure (lane 9) some bands were visible, but none corresponded to the two predominant start sites found in the presence of S100 extract. Thus, by the run-off assay, the *in vitro* system seems to allow specific initiation of RNA polymerase B at or near the major early cap sites used *in vivo* (a) and at a site about 80 base pairs downstream (b). Handa and co-workers¹⁵, using a HeLa whole-cell extract, have also detected initiation of transcription in these two regions of SV40.

S_1 nuclease mapping gave a more precise determination of the *in vitro* start sites corresponding to run-off band a. The early

Fig. 3 S_1 nuclease mapping of the 5' ends of RNAs from infected CV1 cells or transcribed *in vitro* in the presence of the HeLa extract. Poly(A)⁺ cytoplasmic RNA was isolated from 30-h-infected CV1 cells as described in ref. 13. pSV3 transcripts were synthesized in HeLa extracts as in Fig. 2 (*HpaII*-*TaqI* template) and purified free of DNA as already described³. In all cases, 2.5-fold reactions were used for the mapping of *in vitro* transcripts. S_1 nuclease mapping, using a single-stranded *HpaII*-*HinfI* probe ³²P-5'-end labelled at the *HinfI* site (Fig. 1a), essentially was performed as in ref. 13. **a**, Lanes 2-4, fragments protected by 30-h-infected CV1 cell RNA after 3 h of treatment with 500 (lane 2), 1,000 (lane 3) or 2,000 (lane 4) U ml^{-1} of S_1 nuclease; lanes 5-8, fragments protected by *in vitro*-synthesized RNA after 3 h of treatment with 2,500 U ml^{-1} S_1 nuclease. The RNA synthesis reactions contained pSV3 *EcoRI* fragment and the S100 extract in standard conditions (lane 5), pSV3 *EcoRI* fragment and S100 in the presence of $1 \mu\text{g ml}^{-1}$ α -amanitin (lane 6), S100 in the absence of pSV3 template (lane 7) and pSV3 template in the absence of S100 (lane 8). Lanes 1 and 9 show an A+C sequence ladder of the SV40 *HpaII*-*HinfI* fragment²⁸. **b**, Lane 2, same as lane 4 of **a**; lanes 3-9, same as lane 5 of **a**, except that the NTP concentrations during the RNA synthesis reaction were 10 μM GTP and 200 μM CTP, ATP, UTP (lane 3), 10 μM CTP and 200 μM GTP, ATP, UTP (lane 4), 10 μM GTP, CTP and 200 μM ATP, UTP (lane 5), 10 μM ATP and 200 μM GTP, CTP, UTP (lane 6), 10 μM UTP and 200 μM ATP, GTP, CTP (lane 7), 10 μM UTP, ATP and 200 μM GTP, CTP (lane 8), 200 μM GTP, ATP, CTP and UTP (lane 9). Lanes 1 and 10 show an A+C sequence ladder of the SV40 *HpaII*-*HinfI* fragment²⁸.

coding strand of an *HpaII*-*HinfI* fragment (Fig. 1a), ³²P-end labelled at the *HinfI* site, was hybridized with either poly(A)⁺ cytoplasmic RNA from SV40-infected CV1 cells or RNA transcribed *in vitro* from the *HpaII*-*TaqI* fragment. The hybrids were treated with nuclease S_1 , denatured and electrophoresed on a sequencing gel. Progressively stronger S_1 treatment (Fig. 3a, lanes 2-4) shows that the DNA fragments protected by RNA synthesized *in vivo* has a complex pattern consisting of three components: R1, a cluster of bands mapping between nucleotides 5,189 and 5,197; R2, two bands, at positions 5,175 and 5,177; R3, two clusters of bands mapping at nucleotides 5,164-5,166 and 5,169-5,173. The bands in regions R1 and R2 decrease in intensity with stronger S_1 treatment, while the R3 bands increase. Most of the R1 and R2 bands map within a 27-base hairpin centred at the *BglII* site (Fig. 1c) and we suggest that the transient bands result from S_1 'pauses' in regions of extensive DNA secondary structure (this interpretation has been proposed to explain a similar phenomenon arising during S_1 mapping of conalbumin gene transcripts³). With this assumption we conclude that the major *in vivo* early cap sites fall within the region 5,164-5,166 and 5,169-5,173. S_1 mapping does not allow us to assign single-base start sites because S_1 trimming (according to the severity of digestion conditions) can result in 3'-ragged DNA with an overhang of 1-5 nucleotides¹⁶⁻¹⁹. Nevertheless, our assignment of the major *in vivo* early cap sites agrees with previously published results using reverse transcriptase primer extension mapping²⁰ or enzymatic cap analysis^{13,21}.

S_1 mapping of the *in vitro*-synthesized RNA results in an essentially identical pattern of protected fragments (Fig. 3a, lane 5), suggesting that RNA polymerase B initiates faithfully at the major *in vivo* cap sites, although a low amount of *in vitro* initiation may occur in regions 1 and 2. These S_1 -protected fragments were not observed when $1 \mu\text{g ml}^{-1}$ α -amanitin was included in the RNA synthesis reaction (Fig. 3a, lane 6), and they require the presence of DNA in the S100 extract (Fig. 3a, lane 7). In the absence of S100 extract (Fig. 3a, lane 8), initiation occurs at multiple sites throughout the fragment.

During these studies we noted a strange phenomenon related to the concentration of nucleotide triphosphates (NTPs) included in the *in vitro* RNA synthesis reaction. As described above, the major start sites *in vitro* consist of two clusters of bands (R3); however, this is not true if the concentration of purines in the synthesis reaction greatly exceeds that of pyrimidines or vice versa. For example, when GTP (or ATP) is present at 10 μM and the other three NTPs at 200 μM , the upper cluster of bands in R3 is much more prominent (Fig. 3b, lanes 3, 6). In contrast, when CTP (or UTP) is included at 10 μM and the other three NTPs at 200 μM , the lower cluster predominates (Fig. 3b, lanes 4, 7). Only if the total purine concentration approximates the total pyrimidine are both clusters of bands observed in a ratio similar to that found with *in vivo* RNA (Fig. 3b, compare lane 2 with lanes 5, 8 and 9). Although we cannot explain this phenomenon, it does suggest that our S_1 mapping detects true RNA polymerase start regions, as it is unlikely that the NTP concentration affects anything other than the *in vitro* RNA synthesis reaction. Also, any *in vitro* study of mutant promoter regions must consider this NTP concentration effect.

S_1 mapping of the RNA represented by run-off fragment b using the *EcoRII* G fragment (Fig. 1a) (data not shown) shows that the 5' end of the b transcript maps around nucleotide 5,080. Bands were not detected at this site in S_1 mapping of *in vivo* wild-type RNA even on heavily overloaded gels (although a band at 5,085 can sometimes be observed; data not shown). A 5'-GATAAA-3' sequence occurs 15 base pairs upstream from position 5,080, and a hairpin spans nucleotides 5,100-5,120 (centred ~30 base pairs upstream from the start site). We do not know whether either of these sequence elements corresponds to an initiation signal recognized *in vitro* but not *in vivo*.

Thus, we have shown that RNA polymerase B initiation on the SV40 early region occurs *in vitro* at a limited number of sites,

Fig. 4 Run-off analysis of RNA transcribed *in vitro* from deletion mutants in the promoter region. The construction of the wild-type plasmid pSV1 and the derivation of plasmids bearing deletions in the promoter region are described in ref. 13. Each of these recombinants was cut by *TaqI* and *HpaII* to provide an SV40 early region truncated template. The fragments were purified on sucrose gradients and then incubated for RNA synthesis in the presence of the HeLa S100 extract. The incubation conditions and subsequent analysis of transcripts were exactly as described in Fig. 2 legend. The RNA synthesis reactions contained for lanes 2 and 16: $4 \mu\text{g ml}^{-1}$ of the 850-base pair *EcoRI* fragment from pSV3; for lanes 3 and 4, 4 and $8 \mu\text{g ml}^{-1}$, respectively, of the *HpaII-TaqI* fragment from pSV1; for the remaining lanes: 2, 4 or $8 \mu\text{g ml}^{-1}$ of the *HpaII-TaqI* fragment from AS (lanes 5–7), HS0 (lanes 8–10), HS3 (lanes 11–13), HS4 (lanes 17–19), HS2 (lanes 20–22) or HS105 (lanes 23–25). The arrows in lanes 18 and 19 indicate the position of the band *a* transcripts visible on the original autoradiogram. All samples were derived from the same experiment although they were electrophoresed on two gels (lanes 1–14 and 15–25). The markers in lanes 1, 14 and 15 were ^{32}P -5'-end labelled *HpaII* fragments from pBR322.

one prominent set corresponding to the major cap sites used *in vivo*. Transcription seems rather inefficient, however, being about 20% that of the Ad-2 major late transcription unit in the same conditions (data not shown). Nevertheless, the fidelity of initiation with the HeLa cell-free system allows us to approach the question of whether mutations in the promoter region affect *in vitro* and *in vivo* initiation of transcription identically.

Some *in vivo* transcription signals are recognized *in vitro* by RNA polymerase B

The accompanying article¹³ describes the construction of a series of deletion mutants spanning the promoter region for the SV40 early genes. Deletions were of three types (Fig. 1b): (1) those removing sequences between the TATA box and the major *in vivo* cap sites (for example, AS), (2) those which start at position 5,162, delete the major cap sites and extend upstream towards and eventually beyond the TATA box (the HS series), and (3) those starting from the *HpaII* site at position 282 and extending downstream towards the TATA box (the PS series). RNA synthesized *in vivo* by the first two classes of mutants indicated that one function of the TATA sequence was to fix initiation of transcription within a narrow region¹³. In its presence, RNA polymerase B starts transcription about 30 base pairs downstream; in its absence, the enzyme initiates at multiple sites over a broad region. We now assess the effect of these promoter region deletions on *in vitro* RNA synthesis.

HpaII-TaqI fragments purified from the wild-type 'parental' plasmid pSV1 and from the various mutants, were transcribed *in vitro* and the run-off RNA transcripts analysed as described above (Fig. 2) for wild-type plasmid pSV3. (Note that pSV3 contains the SV40 early sequences *HpaII-TaqI* inserted at the *EcoRI* site of pBR322, whereas pSV1 contains the *HpaII-BamHI* sequences inserted at the same site.) Incubation of the pSV1 fragment in the cell-free system resulted in the expected

500 (*a*) and 420 (*b*) base pair run-off bands (Fig. 4, lanes 3, 4). Some bands not observed with the other wild-type plasmid—pSV3—were also evident (compare lanes 2 and 4), but these are not α -amanitin sensitive (data not shown) and probably correspond to full-length transcripts of contaminating DNA fragments [*HpaII-TaqI* sequences are easier to purify from pSV3 than from pSV1 or the various deletion mutants, especially when large deletions are involved (see Figs 2 and 4 legends for details)].

Mutants AS, HS0, HS3 and HS4 all retain the TATA box, although only AS retains the major *in vivo* cap sites (Fig. 1b). Run-off transcripts *a* and *b* are clearly produced when AS (Fig. 5, lanes 5–7), HS0 (lanes 8–10) and HS3 (lanes 11–13) fragments are incubated in the cell-free system. With HS4 (lanes 17–19), the *a* and *b* bands are both detectable, at least on the original autoradiogram, but *a* is much reduced. Closer inspection of the data reveals that with deletions which do not involve the TATA box (1) the size of band *a* decreases progressively with larger deletions, and (2) the ratio of *a* to *b* is different with the various mutants. Densitometric scanning of the autoradiograms indicates the following *a/b* ratios: pSV1 or pSV3, 1.0; AS, 2.5; HS0, 6.5; HS3, 1.0; HS4, 0.25. This effect has been observed in several experiments using different DNA preparations and varying NTP concentrations.

Mutants HS2 and HS105, which lack both the TATA box and the major *in vivo* cap sites (Fig. 1b), do not express an *a* transcript (lanes 20–22 and 23–25), although band *b* is readily apparent (a result obtained with several different DNA preparations and in all NTP conditions studied).

Using *S*₁ nuclease mapping to compare the effect of promoter region deletions on initiation *in vitro* and *in vivo* (Fig. 5a), we found that for those mutants which retain the TATA box (AS, HS0, HS3 and HS4), the major *in vivo* start sites are mimicked quite faithfully *in vitro*. In both environments, RNA polymerase B initiates about 30 base pairs downstream from the TATA box,

Fig. 5 S_1 nuclease mapping of 5' ends of RNAs synthesized *in vivo* or *in vitro* from mutant plasmids. Poly(A)⁺ cytoplasmic RNA was isolated from rat 3T3 cells transformed by the various mutants as described in ref. 13. S_1 mapping was as in Fig. 3 except that *HpaII-HinI* probes specific for each mutant were used. **a**, The cellular RNAs were from cell lines transformed by pSV1 (lane 2), AS (lane 3), HS0 (lane 5), HS3 (lane 7) or HS4 (lane 9). The *in vitro* RNA synthesis reactions contained *HpaII-TaqI* fragments from plasmids AS (lane 4), HS0 (lane 6), HS3 (lane 8) and HS4 (lane 10). Lanes 1 and 11 show an A+C sequence ladder²⁸ from the wild-type *HpaII-HinI* fragment. **b**, The cellular RNAs were from cell lines transformed by HS2 (lane 4) and HS105 (lane 5). The *in vitro* RNA synthesis reactions contained *HpaII-HhaI-TaqI* fragments from plasmids HS2 (lane 1) and HS105 (lane 2) (for mutants with long deletions, *HhaI* digestion was performed to facilitate separation of the SV40 fragment from contaminating pBR322 sequences). Lane 3 shows an A+C sequence ladder²⁸ from the wild-type *HpaII-HinI* fragment. The numbers to the left refer to nucleotide sequence number as in Fig. 1a; the numbers to the right correspond to band numbers in Fig. 3b of ref. 13. **c**, The *in vitro* RNA synthesis reactions contained *HpaII-HhaI-TaqI* fragments from HS105 in standard conditions (lane 1) in the absence of S100 (lane 2) or in the presence of $1 \mu\text{g ml}^{-1}$ α -amanitin (lane 3). For lane 2, only 1/8 of the S_1 -protected material was loaded.

regardless of the exact downstream sequences (ref. 13 gives a precise map of the *in vivo* start sites for these mutants). There are some differences in the RNAs synthesized *in vivo* and *in vitro*: for HS0, the ratio of the two starts differs in the two environments; for HS3 the *in vitro* start sites appear to extend further downstream than those of *in vivo* RNA. The experiments depicted in Fig. 5 give no indication of the efficiencies of transcription, as DNA probes of different specific activity were used for each mutant. However, S_1 -mapping of the mutant transcripts using a single wild-type probe (data not shown) shows that the level of initiation just downstream from the early region TATA box varied for different mutants, in the order HS0 > AS > HS3 $\approx$ PSV1 > HS4.

When the TATA box is deleted, early gene expression can still be detected *in vivo*, but transcription begins at multiple sites over a broad area¹³, and S_1 mapping experiments (Fig. 5b, c) demonstrate that this phenomenon also occurs *in vitro*. (This multiplicity of initiation sites probably explains why no distinct bands can be detected by the run-off assay; see above.) For a given mutant, the pattern of fragments protected by *in vitro*-synthesized RNA closely resembles that of fragments protected by *in vivo* transcripts (compare lanes 1 and 4 or lanes 2 and 5; see also Fig. 3b in ref. 13). Most bands are observed with both *in vivo* and *in vitro* RNAs, although relative band intensities differ, sometimes markedly. Using a single wild-type probe we also determined that the *in vitro* transcription of HS2 is not much less than that of the wild-type plasmid pSV1 (data not shown),

although the new set of cap sites generated in HS2 was not detected for pSV1, indicating that, as *in vivo*¹³, the wild-type TATA sequence may 'mask' its functional substitutes. We do not know whether these 'substitute' elements are preferentially located in the early promoter region or scattered throughout the SV40 genome.

Figure 5c shows that RNA polymerase B alone selects specific initiation sites, but yields a very heterogeneous pattern (lane 2). Some factor(s) of the S100 extract restricts initiation to a few of these sites (lane 1), producing a similar pattern to that seen *in vivo*. It also requires RNA polymerase B, being abolished by the inclusion of $1 \mu\text{g ml}^{-1}$ α -amanitin in the RNA synthesis reaction (lane 3).

We therefore conclude that some of the initiation 'signals' recognized *in vivo* by RNA polymerase B are also recognized *in vitro*. Initiation occurs about 30 base pairs downstream from the TATA box when it is present, but at many sites over a broad area when it is deleted. The 'fixing' function probably includes the TATA box because initiation ~ 30 base pairs downstream is already reduced in HS4, which has a deletion end point just 2 base pairs downstream from the TATTTAT sequence (Fig. 1c), but we cannot exclude the possibility that other sequences, deleted in HS2 but present in HS4 (Fig. 1c), are involved.

'Signals' controlling initiation by RNA polymerase B *in vivo* do not operate *in vitro*

The third class of deletion mutants described in the accompanying article¹³, the PS series, retains the major wild-type cap sites as well as a normal TATA box, but lacks sequences further upstream. Analysis of the *in vivo* expression of PS mutants

Fig. 6 Run-off analysis and S_1 nuclease mapping of RNA synthesized *in vitro* from the deletion mutant PS366. The construction of PS366 is described in ref. 13. **a**, Run-off analysis was as in Fig. 2. Lane 2, the *HpaII-TaqI* fragment from pSV1 was incubated with S100 extract in standard conditions. Lane 3, the same fragment incubated with S100 in the presence of $1 \mu\text{g ml}^{-1}$ α -amanitin. Lane 4, the *HpaII-HhaI-TaqI* fragment from PS366 was incubated with S100 in standard conditions. Lane 5, the same fragment was incubated with S100 in the presence of $1 \mu\text{g ml}^{-1}$ α -amanitin. Lane 1 shows a ^{32}P -5'-end-labelled *HpaII* digest of pBR322. **b**, S_1 nuclease mapping was as in Fig. 5. Lane 1, fragments protected by RNA synthesized *in vitro* from the pSV1 template; lane 2, an A+C sequence ladder²⁸ of the wild-type *HpaII-HinI* fragment; lane 3, fragments protected by RNA synthesized *in vitro* from the PS366 template. R3 refers to the region delineated in Fig. 3a.

indicates that sequences mapping in the region of the two 72-base pair repeats I and II (Fig. 1b) markedly affect early gene expression. For example, PS366, which lacks nucleotides 98–282 and thus more than one complete copy of the 72-base pair repeat (Fig. 1b), does not detectably express the early genes during short-term infection of CV1 cells, and transforms rat 3T3 fibroblasts much less efficiently than a wild-type plasmid. However, Fig. 6a demonstrates that, by the run-off assay, *in vitro* transcription of PS366 is not similarly inefficient. The *a* transcript is readily apparent when an *HpaII*–*TaqI* fragment from PS366 is transcribed in the HeLa cell-free system (lane 4). Furthermore, S₁ nuclease mapping reveals that RNA polymerase B initiates the *a* transcript at the same sites on PS366 as on the wild-type pSV1 (Fig. 6b, lanes 1, 3). Thus, those sequence elements in the region of the 72-base pair repeats that exert a crucial influence on *in vivo* expression have no apparent effect in an *in vitro* environment.

***In vitro* and *in vivo* promoter regions for RNA polymerase B**

The three DNA sequence elements implicated in the control of initiation of transcription by RNA polymerase B are the TATA box region^{3,5,10,11,13}, the cap site region^{5,11} and a region upstream from the TATA box (refs 11–13, and personal communications from R. Grosschedl and M. L. Birnstiel, and from R. Kamen).

The present report and the accompanying one suggest that, both *in vivo* and *in vitro*, the early gene TATA box (or closely adjacent sequences) functions to limit initiation to a narrow region. In its presence, RNA polymerase B starts transcription about 30 base pairs downstream, and a similar function has been noted for other genes^{5,11,13,22}. Whatever actually measures the TATA box–cap site distance operates quite accurately *in vitro*, even in a heterologous system, for the newly selected cap sites on mutant templates are similar to those used in mammalian cells. The finding that on deletion of the early gene TATA box RNA polymerase initiates at multiple sites over a broad region both *in vitro* and *in vivo* is in keeping with a report that, in *Xenopus* oocytes, initiation occurs at multiple sites on an injected sea urchin histone gene lacking its normal TATA sequence¹¹. The multiple initiation sites we observe are nearly identical to those found *in vivo* (Fig. 5b), and this specific pattern is dependent on the presence of some factor(s) present in the cell-free extract (Fig. 5c), suggesting that the factor(s) which recognize the TATA box could also recognize its functional substitutes. Deletions or single-point mutations involving the TATA box have been reported to abolish, or drastically reduce, *in vitro* transcription^{5,10}, but such studies relied mainly on the run-off assay, and we also were unable to detect transcripts from the TATA-minus mutants using this assay. Alternatively, it is possible that some genes, like the SV40 early region, have sequences which can substitute functionally for the TATA box, while other genes either do not have them or have sequences which function much less efficiently than the TATA sequence.

We have observed that in mutants retaining the TATA box, the newly selected cap sites seem to be used with varying efficiencies *in vitro*, and this has been attributed^{5,11} to control by sequences around the cap site. We cannot decide whether the crucial sequences are those at the cap site and/or those between the TATA box and start site. Clearly, the mere presence of purines around the initiating nucleotide is not the important factor, because initiation on both HS0 and HS4 occurs in a region rich in purines. (*In vivo* transcription of many genes by RNA polymerase B starts with an A within a pyrimidine-rich region^{5,9}.) Nucleotides between the TATA box and the start sites might well influence the efficiency of cap site utilization, especially for the SV40 early genes, where a 27-base hairpin normally separates the TATA and the cap site (Fig. 1c). It is possible that AS and HS0 are transcribed so efficiently merely because this hairpin is disrupted, and that HS4 is transcribed much less efficiently because its longer deletion begins to affect the TATA box function. Interestingly, similar 'up'-mutations have been noted *in vivo*. Rat cells transformed by plasmids

bearing deletions 10–15 base pairs downstream from the early gene TATA box produce more early mRNA than cells transformed by wild-type plasmid (see ref. 22 and the accompanying article). Gluzman *et al.*²² have suggested that this overproduction of early mRNA might be due to a failure in autoregulation by T antigen. In light of the *in vitro* results, it might, instead or in addition, be caused by a more efficient utilization of the newly selected cap sites.

The far upstream sequences¹³, which are required *in vivo* but not *in vitro*, might bind RNA polymerase directly (analogous in some respects to the prokaryotic 'recognition site'²³), might dictate chromatin structure directly²⁴ or indirectly, or might bind activator proteins. We have shown that the mutant plasmid PS366, which lacks certain sequences upstream from the TATA box and is expressed inefficiently *in vivo*, is transcribed quite readily in the HeLa cell-free extract. The level of initiation approximates that for wild-type plasmid and the start sites are those normally used. This observation tends to argue against a model whereby the upstream sequences exert their influence simply by binding polymerase. However, the efficiency of transcription *in vitro* is much lower than *in vivo*^{1–5}, and it is possible that the mode of polymerase binding differs in the two environments. It may be that the chromatin structure in the promoter region brings into close vicinity the TATA box and the upstream sequences and that accurate reconstruction of chromatin structure might be important in understanding the role of the upstream sequences. We do not know the state of the DNA after incubation in the S100 extract, but it is unlikely to be packaged in chromatin as it is *in vivo*, for we have observed that during the standard RNA synthesis reaction supercoiled DNA templates are converted to relaxed covalently closed circles (unpublished results), whereas if nucleosomes had been formed, supercoiled DNA should have been recovered^{23,24}. Certainly, activator proteins could also be missing from the cell-free system. Clues as to how the upstream sequences control initiation *in vivo* and why they do not exert a similar influence *in vitro* await further experimentation.

We thank Drs C. Benoist, B. Davison and C. K  dinger for the gift of materials and for helpful advice, Mr J. M. Garnier for technical assistance, and Ms B. Chambon, C. Kutschis and Mr B. Boulay for help in preparing the manuscript. This work was supported by grants from the INSERM (ATP 72.79.104, CL 801029 and CL 801033), the CNRS (ATP 'Biologie Mol  culaire de G  ne'), the Fondation Fran  aise pour la Recherche M  dicale and from the Fondation S. and C. Del Duca.

Pulsar and diffuse contributions to observed galactic γ radiation

A. K. Harding & F. W. Stecker

Laboratory for High Energy Astrophysics, NASA/Goddard Space Flight Center, Greenbelt, Maryland 20771, USA

Satellite data on the energy spectrum of galactic γ -radiation^{1,2}, shows that such radiation has a multicomponent nature³⁻⁷. Here we use a calculation of the pulsar γ -ray emission spectrum together with a statistical analysis of recent data on 328 known pulsars to make a new determination of the pulsar contribution to galactic γ -ray emission. We then re-examine the contributions from diffuse interstellar cosmic-ray induced production mechanisms to the total emission and conclude that pulsars may account for a significant fraction of galactic γ -ray emission.

Models for the production of high-energy γ rays in the Galaxy have dealt primarily with diffuse emission processes, those which involve interactions between cosmic rays and interstellar matter. The major contributions are thought to come from electron bremsstrahlung and the decay of neutral pions produced in high energy proton collisions, with a small additional flux from Compton interactions. In determining the relative contributions of these processes from the shape of the observed γ -ray spectrum, the contribution of true point sources (as opposed to enhancements in the spatial distribution from diffuse processes) has been neglected, largely because the point source spectrum has been undetermined. At present, pulsars can give the best information on a true point source component of the galactic γ -ray flux.

We report here on the first calculation of a γ -ray production spectrum from pulsars in the Galaxy and on the implications of this point source contribution to the general interpretation of the observed galactic γ -ray spectrum. The details of this calculation, as well as a determination of the longitude and latitude profiles of pulsar γ rays will be described elsewhere⁸. There have been previous estimates of the pulsar contribution to the observed galactic γ -ray flux⁹⁻¹¹, using only 51 pulsars and very general assumptions about their γ -ray luminosities. There are now 328 known radio pulsars, all having independent distance determinations through their dispersion measures. The local density and galactic distribution can therefore be much better determined, assuming a value for the mean free electron density in the galactic plane. Pulsed γ rays have been observed from the Crab (PSR0531+21) and Vela (PSR0833-45) pulsars by the SAS 2 satellite^{12,13}, and the COS B satellite¹⁴. The energy spectra of these sources have recently been determined in the range 50 MeV–2 GeV and they can both be fit with steep power laws of similar slope around -2 (ref. 15). Although these two young sources represent only a small fraction of the known pulsars, their emission testifies to the fact that some, and possibly all pulsars are γ -ray emitters at some stage of their evolution. Though these others may be individually below the present limits of detectability, the contribution of their γ rays to the observed galactic emission could be significant, as has been previously suggested⁹.

We assume that the γ -ray emission above 100 MeV is produced by curvature radiation from primary particles which have been accelerated to high energies in the electric fields of the pulsar's magnetosphere. Some of these γ rays are converted to electron-positron pairs in the strong pulsar magnetic field. The electric field induced perpendicular to the magnetic field by the star's rotation also contributes to the pair production rate and has a large effect on the optical depths in short period pulsars¹⁶. The shape of the numerically calculated spectra in this model

depend on the initial energy of the primary particles and on the pulsar magnetic field strength and period¹⁷. For an initial energy of 1.5×10^4 GeV and a field strength of 10^{12} G, the resulting calculated spectrum for a pulsar period of 0.033 s reproduces the shape of the observed Crab pulsar spectrum. The observed 100-MeV flux from the Crab pulsar at 2 kpc is used to determine the normalization factor ($\sim 10^3$) which is the ratio of the primary particle density above the polar cap to the corotation charge density. Using this same normalization factor, primary particle energy, and magnetic field strength, the calculated spectrum for a period of 0.089 s fits the observed Vela pulsar spectrum quite well. It may be reasonable to assume, then, that these values of the parameters determining the spectrum are valid for all pulsar periods.

An expression for the γ -ray luminosity can be derived by integrating the spectra calculated for different periods, P , and surface magnetic field strengths, B_{12} (in units of 10^{12} G). The best fit for the dependence of luminosity on these quantities gives:

$$L_{\gamma}(>100 \text{ MeV}) = 1.2 \times 10^{35} B_{12}^{0.95} P^{-1.7} \text{ photons s}^{-1} \quad (1)$$

The γ -ray luminosities and fluxes for the known radio pulsars have been calculated from equation (1) and compared with the upper limits obtained by SAS 2 (ref. 18) and the sources in the COS B catalogue¹⁹. Eight pulsars have predicted fluxes above the point source detectability limit of COS B but most are towards the galactic centre where the diffuse background is high. Only two lie in the longitude range $90^\circ < l < 270^\circ$ where the search is considered complete down to $1.3 \times 10^{-6} \text{ cm}^{-2} \text{ s}^{-1}$; however, they both lie just outside the latitude range of the search. Four pulsars have predicted fluxes above their SAS 2 upper limits, but exceed them by no more than the estimated uncertainties in either the measurements or the model.

Fig. 1 Differential production spectra for pulsars and the major diffuse processes. The π^0 , bremsstrahlung and Compton spectra are from refs 6, 26 and the total spectrum includes the pulsar contribution. SAS 2 and COS B data points for the longitude range $355^\circ < l < 15^\circ$ are also shown ($\diamond$, ref. 2; $\bullet$, ref. 1). The left- and right-hand scales refer to the theoretical production rates at 10 kpc from the galactic centre and the observed γ -ray flux, respectively.

In calculating these pulsar spectra and luminosities, it has been assumed that the magnetic field is a pure dipole and that the angle between the dipole axis and spin axis is 90° , because we are concerned here with the collective properties of the pulsar population, and a random distribution of angles would give an average of 90° . More details of the model are given in ref. 17.

If all pulsars produce pulsed γ rays according to this model, then the local differential production spectrum will be,

$$q_{\text{PSR}}(E_\gamma) = \frac{D_\odot}{2h} \int_0^\infty I_\gamma(P, E_\gamma) \rho(P) dP$$

where $D_\odot$ is the local surface density of pulsars which are beamed in our direction, h is their scale height above the plane, $\rho(P)$ is their period distribution and $I_\gamma(P, E_\gamma)$ is the γ -ray spectrum of an individual pulsar with period P . $I_\gamma(P, E_\gamma)$ is also directly proportional to surface magnetic field strength, so that q_{PSR} will be proportional to the average pulsar magnetic field strength. We take an average field of 10^{12} G, which is consistent with measured pulsar spindown rates. The derived local density and scale height depend on a determination of $\langle n_e \rangle$, the mean electron density in the galactic plane, which, through dispersion measure observations, fixes the pulsar distance scale. Unfortunately, the galactic distribution of n_e is not well known and is difficult to determine. There are several indications that n_e is not uniform throughout the galactic plane and that it does not have a simple exponential Z dependence^{20,22}, both of which have been previously assumed in determining pulsar densities. However, in view of the difficulties entailed in a detailed spatial modeling of n_e , given the present observational data, we adopt the simple constant density model of Taylor and Manchester²³ which is sufficient for estimating the mean contribution from pulsars to the galactic γ -radiation. For $\langle n_e \rangle = 0.03 \text{ cm}^{-3}$, a value consistent with H I absorption distances to pulsars in local regions of the Galaxy²⁰, a statistical analysis of data on the 328 known pulsars gives $D_\odot = 480 \text{ pulsars kpc}^{-2}$ and $h_p = 325 \text{ pc}$. The resulting γ -ray production spectrum per cm^3 is shown in Fig. 1 along with the production spectra for the major diffuse processes calculated⁶, assuming a local interstellar hydrogen density of 1 atom cm^{-3} . This spectrum gives volume-averaged integral pulsar γ -ray production rates at 10 kpc of 2.2×10^{-26} photons $\text{cm}^{-3} \text{ s}^{-1}$ above 100 MeV and 4.6×10^{-26} photons $\text{cm}^{-3} \text{ s}^{-1}$ above 35 MeV. Although the calculated pulsar spectrum has been extrapolated below 100 MeV, the model does not accurately predict the low energy spectrum because the synchrotron radiation from secondary particles, which may extend to the γ -ray region, has not been included. This contribution would tend to steepen the spectrum and increase the estimated flux level below around 100 MeV.

The diffuse production spectra in Fig. 1 have widely differing uncertainties. The pion production spectrum is least uncertain, because it primarily involves cosmic ray protons with energies in the range 1–10 GeV where uncertainties in determining galactic fluxes owing to solar modulation effects produce small uncertainties ($\leq 15\%$) in the total production rate²⁴. Even the differential γ -ray source spectrum for $E_\gamma \leq 10 \text{ GeV}$ is insensitive to the kinematical model chosen, as shown by the excellent agreement between calculations given in refs 24–28.

The Compton production mechanism produces only a small expected contribution in our region of the Galaxy, however, this process could be significant near the galactic centre⁶. As this component is small over most of the galaxy and various theoretical estimates^{29,30} are in reasonable agreement with Fig. 1, we conclude that little error in determining the total galactic flux is introduced by the Compton process.

The situation is quite different in the case of electron bremsstrahlung. The curve shown in Fig. 1 for this component was determined using a conservative 'standard' cosmic ray electron spectrum³¹. However, the electron spectrum cannot be easily determined from cosmic-ray data due to large solar modulation effects. Theorists have thus had much leeway in invoking large electron fluxes to account for discrepancies in both the spectrum and intensity of the observed galactic γ rays with 'standard'

Fig. 2 Surface density of pulsars (solid line)⁸ and γ -ray surface emissivity (dashed line)⁶ plotted against galacto-centric radius R for northern and southern halves of the Galaxy.

predictions^{32,33}. Indeed, spectral data have been used to speculate on drastic fluctuations in both electron and proton fluxes in the Galaxy³⁴, although we believe that inherent systematic errors as well as statistical errors in the spectral data make such a radical analysis unwarranted.

The present calculated pulsar contribution has clear implications for analysing the total galactic spectrum. Pulsars contribute a soft power law flux component similar to that expected from electron bremsstrahlung. In addition, the pulsar component as estimated in Fig. 1 is as large as the 'standard' bremsstrahlung component.

We also expect that the pulsar contribution to the total galactic flux should be roughly independent of galactic longitude except in the outer Galaxy. We have used the longitude and distance data for the full sample of observed pulsars, together with corrections for selection effects, to determine the radial distributions of pulsars in both the northern ($0^\circ < l < 180^\circ$) and southern ($180^\circ < l < 360^\circ$) galactic longitudes. The results for the inner Galaxy ($R \leq 8 \text{ kpc}$) are strikingly similar to the distributions of total γ -ray emissivity determined previously⁶. Thus, the ratio of pulsar to total emissivity (the fraction of the flux from the pulsar component) should be roughly constant with longitude, for longitudes within 60° of the galactic centre. This fraction is calculated to be 15–20% above 100 MeV (as derived from both Fig. 1 and a comparison of the longitude distribution of pulsar and observed γ -ray emission⁸ using the data in Fig. 2). It can easily be of the order of 50% at lower energies (see Fig. 1), removing the need to invoke large low-energy electron fluxes to explain the shape of the observed γ -ray spectrum.

The latitude distribution of pulsar γ -ray emission will be narrow but will extend somewhat beyond $b = 10^\circ$ (ref. 8). Pulsars may therefore be able to account for some of the flux observed^{35,36} at galactic latitudes above 10° . According to the model, the younger pulsars are the strongest γ -emitters. They are also more confined to the galactic plane³⁷. Thus, the pulsars at high b have a higher mean age and are weaker. This would be consistent with the lack of observed point sources at high b .

We conclude therefore that the integrated flux from distant γ -ray emitting pulsars may provide an important fraction of the low- to medium-energy galactic γ -ray flux (although a smaller fraction of the flux above 100 MeV), and the inclusion of the

pulsar component in analysing the galactic γ -ray spectrum supports a coherent integrated relationship with galactic cosmic-ray theory as discussed elsewhere³⁸⁻⁴².

The discovery¹ of radio structure on a scale of 10–50 m arc s in SS433 has prompted us to monitor the object with the European VLBI network. The first observations in this programme were made for periods of 9 and 10 h at a wavelength of 6 cm on 9 January (JD2444248) and 1–2 June (JD2444392.5) 1980. Our results, together with the observations of Walker *et al.*² at an earlier epoch, show that the compact radio structure of SS433 changes orientation in a manner consistent with the 164-day precession period inferred from the optical emission lines, but with a phase delay of 5 ± 4 days. The shape of the radio structure is elongated, non-linear and changes from one observing epoch to the other.

Fig. 1 Loci of the east-west (U) and north-south (V) components of the projected baselines for our 6-cm observations of SS433. The baselines shown are those for which the source was detected: (1) Westerbork-Effelsberg; (2) Chilbolton-Effelsberg; (3) Knockin-Effelsberg.

Signals were recorded with the standard MkII VLBI system (bandwidth 2 MHz) and the cross correlations were performed at the Max-Planck-Institut für Radioastronomie in Bonn. Further observational details are given in Table 1. Useful data were obtained on the Westerbork-Effelsberg baseline in both sessions, on the Chilbolton-Effelsberg baseline for 2 h in January (the source was not detected during the rest of the observation) and on the Knockin (Jodrell Bank) - Effelsberg baseline for the full track in June. Loci of projected baselines for the various interferometers are shown in Fig. 1.

Measurements of calibrator sources were made at regular intervals throughout network periods encompassing the SS433 observations. Based on the flux densities measured at Westerbork and Effelsberg, these data were used to calibrate the performance of the individual interferometers³. In the June session, the unresolved source 2134 + 004 (ref. 4) at declination 0.4° was observed at several intervals during the first and last 3 h of its apparition, to calibrate directly the changing gain, aperture blockage and spillover effects of the various antennas as a function of elevation for SS433 (at dec 4.9°). It was assumed that any differences in the general atmospheric conditions were negligible between observations of SS433 and 2134 + 004. The resulting calibration factors had an r.m.s. scatter of $\sim 5\%$. The point-to-point amplitude scatter for 2 min coherent integrations on the calibrator sources was $\sim 3\%$.

The flux densities of SS433 at 6 cm at the epochs of our measurements have been interpolated from measurements at 11 and 3.7 cm carried out by Johnston *et al.* (personal communication) assuming that the spectrum is a power law⁵. At these epochs, SS433 is classified as being in an inactive phase by Johnston *et al.*, meaning that the radio flux was changing by $< 20\%$ over a period of days. There is evidence that on 1–2 June, the flux density may have decreased by 8% during the period of our observations. We see little evidence of this in our visibility data, and it seems likely that variations of the visibility amplitude with hour angle are due to changes in the projected source structure rather than variations in the flux density.

The calibrated visibility amplitudes for the two sessions are shown in Fig. 2. Most of the information on source structure comes from the Westerbork-Effelsberg baseline, but the longer baselines provide important constraints on the structure. Although there are insufficient data for hybrid maps to be made, the relatively simple fringe amplitude curves allow several basic conclusions to be drawn about the structure and its variation. These conclusions are supported by the results of fitting simple models consisting of one or two barely resolved components and one or two extended elliptical gaussian components to the available data at each of the two epochs. Table 2 gives the parameters of the models and the range of values of each parameter which are consistent with the data. Curves representing the visibility amplitudes of these models are also shown in Fig. 2, and pictorial representations of the models from our data are given in Fig. 3.

The following deductions about the structure can be made.

(1) The size of the amplitude variations on these baselines

Table 1 Some parameters of the observations

Date	UT	Telescopes	Frequency (MHz)	Flux density (mJy)
9 January 1980	0600–1500	Westerbork Effelsberg Chilbolton	4,997	500 ± 20
1–2 June 1980	2045–0700	Westerbork Effelsberg Knockin	5,008.8	330 ± 30

The polarization on the sky was RCP in January and LCP in June.

shows the existence of structure on the 100–200 m arc s scale in both January and June.

(2) In January, the source was completely resolved on the longer projected spacings of the Chilbolton–Effelsberg baseline. The data shown for this baseline are for spacings similar to the Westerbork to Effelsberg baseline at extreme hour angles (see Fig. 1). In June, a barely resolved component of ~100 mJy is evident on the Knockin–Effelsberg baseline and on the Westerbork–Effelsberg baseline for the last 5 h.

(3) The projected baseline at which the peak fringe amplitude occurred for the Westerbork–Effelsberg interferometer differed in position angle (PA) by ~16° between the two observations. This indicates that the dominant PA of the 100–200 m arc s structure changed from $98^\circ \pm 3^\circ$ on 9 January (when it was aligned with the bulges in W50) to $114^\circ \pm 3^\circ$ on 1–2 June.

The following four points refer to the Westerbork–Effelsberg interferometer.

(4) An inflexion near IHA-6.5 h in the June curve, together with the best fitting model listed in Table 2, suggests that although the major part of the June emission was aligned in PA 114°, there is weaker emission still present in the 'fundamental' 98° PA.

(5) The width of the peaks in both curves, as well as their asymmetry, indicate that the structure is non-linear and very elongated.

(6) The difference in shape between the two curves indicates that the general appearance of the radio source changed appreciably between the two observations.

(7) The amplitudes of the maxima indicate that at both epochs the flux density from the compact (≤ 150 m arc s) structure was ~100 mJy less than the total flux density measured for SS433. This 'missing' 100 mJy can reasonably be ascribed to the larger (~3 arc s) structure known to exist from other measurements^{6,7}.

The change in orientation of the compact radio structure may be compared with the predictions of models for SS433 derived from optical observations. On the basis of Abell and Margon's⁸ model, the PA of the precessing jets seen in projection on the sky is expected to vary approximately sinusoidally with time, with a peak-to-peak amplitude of 41.4° and with the same period as the optical emission lines if the jets describe a cone of half angle 20.4° about a mean inclination of 79.7° to the line of sight^{9,10}. Alternatively, the PA has a saw-tooth variation with time (due to the 180° ambiguity in PA) with peak-to-peak amplitude of 172.8° if the angles are interchanged.

The position angles found from our data, and that of Walker *et al.*² on 12 March, 1979 (92° , range 85° – 105°) were compared with the expected behaviour on Abell and Margon's model and found consistent with precession with the smaller cone angle, as predicted by Begelman *et al.*¹¹. If the axis of precession projects onto the sky in position angle 98° (corresponding to the bulges in W50^{10,12,13}) then the PA of radio emission on the scale of 100 m arc s would lag the optical position angle by 5 ± 4 days, and would be phased so that the PA was decreasing in June. Although probably fortuitous, this agrees with the expected delay of about 4.5 days for the radio emitting clouds to reach an angular distance of 50 m arc s, assuming a velocity of 0.26c (ref. 4) and a distance^{10,12,14} of SS433 of 4 kpc (50 m arc s corresponds to a length of 6×10^{15} cm at a distance of 4 kpc).

Fig. 2 The visibility amplitudes for SS433 at 6 cm, as a function of interferometer hour angle. *a*, January 1980, $S_T = 0.5$ Jy; *b*, June 1980, $S_T = 0.33$ Jy. Arrows indicate the hour angles at which a maximum in visibility amplitude is expected for PA 98° and 114° . WSRT, Westerbork; EFF, Effelsberg; CHIL, Chilbolton; KNOCK, Knockin. Errors bars are 2σ .

Our observations provide some evidence for extension of the radio source over a range in PA of $\pm 5^\circ$ to $\pm 10^\circ$ about the dominant PA. The presence of multiple-peaked spectral features have been noted^{9,15} in optical data which could be evidence of remnant emission from previous positions of the beam during its precessional motion. It is not known whether the nonlinearity in the compact radio structure is also due to remnant emission and whether it corresponds to the possible optical remnant emission. Any correspondence will depend on the mechanism for ejecting material into the beams, and also on the lifetimes of the radiating electrons in the different wavelength domains. These factors will affect the persistence of the emission. In the radio domain, the non-thermal integrated spectrum and the high

Table 2 Parameters of the models

Component	Flux (mJy)	Radial distance (m arc s)	PA (deg)	Angular size (m arc s)	Component PA (deg)
<i>a</i> January 1980					
1	89 ± 25	0	0	(92 ± 12) × (1 ± 1)	101 ± 1
2	219 ± 1	10 ± 1	99 ± 3	(22 ± 1) × (1 ± 1)	81 ± 2
3	101 ± 3	65 ± 1	99 ± 1	(22 ± 1) × (1 ± 1)	89 ± 4
<i>b</i> June 1980					
1	134 ± 5	0	0	(163 ± 5) × (12 ± 2)	119 ± 1
2	99 ± 1	0	0	(6.6 ± 0.5) × (5 ± 0.5)	98 ± 1
3	56 ± 5	0	0	(164 ± 5) × (4 ± 1)	98 ± 1

The columns give the component number, the flux density, the radial distance from component 1, the position angle of the location of the component (N to E) with respect to component 1, the major and minor axis, and the position angle of the component. The errors given are formal errors from the model-fitting process; the true errors are probably larger.

brightness temperatures of the compact components, ranging up to 10^9 K (ref. 2), imply that the emission is synchrotron radiation from relativistic electrons. The optical emission line system from the beams seems to arise from gas at a temperature of $<10^4$ K (ref. 11). There are arguments¹⁵ that the lifetime of the optical line emission is ≈ 10 days, but in the radio case there is not enough structural information on which to base calculations of synchrotron lifetimes. These relative lifetimes will also have some bearing on the lag of the rotation of the main axis of the radio emission behind that of the optical.

Although the optical data predict that during the January and June observations, the beams of SS433 lie within 10° of the plane of the sky, the detailed radio structures are different. Further data are required before patterns (if any exist) can be found in the variation of the structure. Radio flares will affect the structure for some time afterwards; note that the January data were taken 8 days after flaring activity in SS433 has ceased while the June data were taken 11 days before the end of the same long

period of quiescent behaviour (K. J. Johnston, personal communication). Perhaps the enhanced compact component in the June data can be identified with a pre-flare buildup of relativistic particles.

We have shown that the 100–200 m arc s structure in SS433 varies in orientation. Although the behaviour is consistent with the precessing beams model, further observations are needed to establish that the change in position angle is indeed periodic. Future comparison of variations in the radio structure and in the optical line emission may well provide unique information about the SS433 phenomenon.

We thank the staffs of the various observatories for their assistance, in particular R. S. Booth and P. N. Wilkinson at the UK telescopes; R. W. Porcas, H. Blaschke and U. Stursberg for advice and assistance during the processing of the data; and K. Johnston for flux density information. The Westerbork Synthesis Radio Telescope is operated by the Netherlands Foundation for Radio Astronomy with the financial support of the Netherlands Organization for Pure Research (ZWO).

Note added in proof: Hjellming and Johnston¹⁶ report extensive VLA observations of SS433 at seven epochs from 8 September 1979 to 20 June 1980. Their maps show an unresolved (≈ 100 m arc s) core source plus elongated 'jet' components up to several arc s in extent. Several of their results bear on the present paper. (1) The PA of the arc s scale structure remains within $\pm 20^\circ$ of 100° , which we have also deduced from our data with reference to the Abell and Margon model. (2) Proper motions observed for several features in the VLA maps have been extrapolated back to show that the radio jets are probably associated with the optical jets in the inner regions. There is some evidence from their data that the radio precession ephemeris lags that of the optical by 10–20 days with an error of the same magnitude. This is consistent with our result. (3) Assuming the core source is spherical, equipartition arguments lead Hjellming and Johnston to synchrotron loss lifetimes of 10^9 s, from which it is concluded that these losses cannot be significant in the core. The structure we derive for the central source is highly elongated implying higher magnetic fields and shorter synchrotron lifetimes. We do not believe that the structural information on the small scales is yet sufficiently good to confidently rule out one or another loss mechanism.

Acetonitrile in the stratosphere—implications from laboratory studies

H. Böhringer & F. Arnold

Max-Planck-Institut für Kernphysik, PO Box 103980, D6900 Heidelberg, FRG

The presence of acetonitrile (CH_3CN) in the stratosphere has been tentatively inferred¹ from measurements of stratospheric positive ions around 36 km. As well as the expected proton hydrates $\text{H}^+(\text{H}_2\text{O})_n$, another ion family was observed to which was assigned the general form, $\text{H}^+\text{X}_l(\text{H}_2\text{O})_m$, where X is a molecule of mass 41 ± 1 AMU. If these ions are formed from proton hydrates by reactions involving the unknown trace gas X, the latter must have a proton affinity of ≥ 175 kcal mol⁻¹ and a number density of the order of 10^5 cm⁻³ around an altitude of 36 km. Two previously proposed identifications for X—NaOH and MgOH—have recently been excluded by new stratospheric ion composition data^{3,4} which unambiguously determined the mass of X to be 41 AMU and failed to show $\text{H}^+\text{X}_l(\text{H}_2\text{O})_m$ ions containing the Mg isotopes 25 and 26. Another suggestion¹ that X might be acetonitrile (CH_3CN) has been criticized on the grounds that it is difficult to explain its presence in the stratosphere². We now report laboratory studies of clustering equilibria for $\text{H}^+(\text{CH}_3\text{CN})_l(\text{H}_2\text{O})_m$ ions, which further support identification of X as acetonitrile.

The measurements were made using a newly designed temperature-variable drift tube mass spectrometer which will be described in detail elsewhere⁵. In this apparatus the primary ions are produced in a separate ion source and are mass selected before they are introduced into the drift tube. The ions traverse the tube drifting in an electric field while they are subjected to reactions with reactant gases. Having passed the drift tube exit aperture the product ions are mass analysed. During the measurements described here the drift tube was operated at low electric fields (≤ 2 V cm⁻¹) so that the additional 'drift energy' of the ions was $< 2\%$ of the thermal energy and only minor temperature corrections have been applied for this effect. The gas pressures applied to the drift tube ranged from 0.2 to 3 torr and the temperatures from 220 to 400 K. Hydrogen was used as buffer gas to which the reactant gas CH_3CN or H_2O was added in amounts of 0.2–10% and the second of the two gases was only added in traces if mixed ligand clusters were to be observed. Primary H_2^+ ions were injected into the drift tube and rapidly converted to H_3^+ by reactions with hydrogen. Proton transfer reactions of these ions led to the core ions H_3O^+ and CH_3CN^+ , which were subjected to further clustering and ligand exchange reactions. We assumed that chemical equilibrium had been established when a further increase of the buffer gas pressure and the reaction time did not change the ratio of product to precursor ion abundance. Absorption and desorption of the reactant gas at the walls of the drift tube made control of the reactant gas pressure difficult and introduced an estimated error of up to a factor of 3 in the measured equilibrium constant.

The $\text{H}^+(\text{CH}_3\text{CN})_l(\text{H}_2\text{O})_m$ ions produced in the laboratory showed all the ion masses observed in the stratosphere by Arnold *et al.*^{1,3}, and essentially all ion masses detected by Arijs *et al.*^{4,6} at an altitude around 34 km (see Table 1). The measured equilibrium constants for association of H_2O and CH_3CN to different cluster ions are given in Fig. 1 for a temperature of 227 K (the ambient temperature during the stratospheric measurement in ref. 3). A comparison of the equilibrium constants for the proton hydrates with previous high-pressure ion source measurements⁷ also given in Fig. 1 shows a fairly good agreement.

The results show that hydration equilibrium constants for heteromolecular clusters containing CH_3CN molecules are generally lower than those for $\text{H}^+(\text{H}_2\text{O})_n$ ions and they decrease with increasing number of CH_3CN ligands contained in the

complex. The equilibrium constants for the $\text{H}^+(\text{CH}_3\text{CN})_p$ ions with $p \geq 3$ are remarkably low despite the large dipole moment of CH_3CN . Thus, it seems that the ligand interaction between H_2O and CH_3CN and among CH_3CN molecules is weaker than that between H_2O molecules which is dominated by hydrogen bonding. This is consistent with the lower heat of evaporation of CH_3CN compared with H_2O .

A striking exception, however, is found for the ion $\text{H}^+(\text{CH}_3\text{CN})_3\text{H}_2\text{O}$ which is the most stable ion containing four ligands and has a much larger equilibrium constant than the two precursors, $\text{H}^+(\text{CH}_3\text{CN})_3$ and $\text{H}^+(\text{CH}_3\text{CN})_2\text{H}_2\text{O}$. Using collision-induced dissociation, we found that decomposition of $\text{H}^+(\text{CH}_3\text{CN})_3\text{H}_2\text{O}$ preferentially leads to the fragment $\text{H}^+(\text{CH}_3\text{CN})_2\text{H}_2\text{O}$, implying that the water molecule is bound more strongly than the acetonitrile molecules. Therefore, the high stability of this ion may be explained by a structural rearrangement, in which H_3O^+ forms the core ion and the acetonitrile molecules are symmetrically attached to the three hydrogen atoms sharing the positive charge. A similarly enhanced stability was found for the ion $\text{H}^+(\text{CH}_3\text{CN})_4(\text{H}_2\text{O})_2$ among the ions with six ligands. An analogous symmetric structure can be attributed to this ion in which the two water molecules attach to the proton leaving four, partly charged H-atom bonding sites for the acetonitrile molecules.

In the stratosphere, hydration is sufficiently fast to attain hydration equilibria for all positive ions. Therefore the hydration equilibria of stratospheric X-containing and laboratory CH_3CN -containing ions can be compared—as shown in Table 2—and a fairly good agreement is found. The laboratory results indicate that among the $\text{H}^+(\text{CH}_3\text{CN})_3(\text{H}_2\text{O})_k$ family, $\text{H}^+(\text{CH}_3\text{CN})_3\text{H}_2\text{O}$ should be the only detectable atmospheric ion, which is, in fact, shown by the stratospheric observations.

The stratospheric observations of H_2O -clustering equilibria are therefore consistent with X being acetonitrile. The only

Fig. 1 Measured equilibrium constants for H_2O and CH_3CN association reactions at 227 K. The equilibrium constants $\geq 10^4$ (torr⁻¹) had to be extrapolated from higher temperatures. For $\text{H}^+(\text{CH}_3\text{CN})_3\text{H}_2\text{O}$ and $\text{H}^+(\text{CH}_3\text{CN})_4(\text{H}_2\text{O})_2$ only lower limits can be given. The results for the proton hydrates are compared with measurements of Kebarle *et al.*⁶. The estimated error of up to a factor of 3 valid for all measured values is indicated by error bars for the first points of the curves. $\circ$, $\text{H}^+(\text{H}_2\text{O})_n$; $\square$, $\text{H}^+\text{CH}_3\text{CN}(\text{H}_2\text{O})_m$; $\triangle$, $\text{H}^+(\text{CH}_3\text{CN})_2(\text{H}_2\text{O})_l$; ∇ , $\text{H}^+(\text{CH}_3\text{CN})_3(\text{H}_2\text{O})_k$; $\bullet$, $\text{H}^+(\text{CH}_3\text{CN})_4(\text{H}_2\text{O})_2$; $\blacksquare$, $\text{H}^+(\text{CH}_3\text{CN})_3$; $\blacktriangle$, $\text{H}^+(\text{CH}_3\text{CN})_4$; $+$, $\text{H}^+(\text{H}_2\text{O})_2(\text{CH}_3\text{CN})_x$ (ref. 6).

exception is the observed ion with mass 136 ± 1 AMU. Assuming that the previous identification, $\text{H}^+(\text{CH}_3\text{CN})_2(\text{H}_2\text{O})_3$, is correct, the ion should be one or two orders of magnitude less abundant than observed. Therefore, this ion could result from reactions involving another trace gas, Y, and thus have the form $\text{H}^+\text{Y}(\text{H}_2\text{O})_i$ or $\text{H}^+\text{YX}(\text{H}_2\text{O})_j$. If this cluster ion contains three or four ligands like the other observed heteromolecular clusters, the mass of the molecule Y should be 99 ± 1 , 81 ± 1 , 76 ± 1 or 58 ± 1 AMU. Possible candidates for Y are CH_3NO_3 (mass 77), $\text{C}_2\text{H}_5\text{CHO}$ (mass 58), and $(\text{CH}_3)_2\text{CO}$ (mass 58) which all have proton affinities in excess of $175 \text{ kcal mol}^{-1}$ and therefore should replace water molecules in proton hydrates in stratospheric conditions. Note that a recently detected⁴ ion of minor abundance with mass 117 AMU may belong to the same hydrate ion family as the ion 136 ± 1 AMU. If so, the mass of Y should be 99, 80, 75 or 57 which would exclude all identifications suggested above.

Table 1 Observed stratospheric positive ions around 36 km altitude

Mass	Identification	Ion mass for $\text{X} = \text{CH}_3\text{CN}$	Measured abundance (%)	
			Ref. 3	Ref. 4
55	$\text{H}^+(\text{H}_2\text{O})_3$	55	3.4	5.5
73	$\text{H}^+(\text{H}_2\text{O})_4$	73	26.8(21.3)*	29.6
78	$\text{H}^+\text{X}(\text{H}_2\text{O})_2$	78	7.2	8.4
91	$\text{H}^+(\text{H}_2\text{O})_5$	91	8.9(17.8)*	2.8

119 ± 1	$\text{H}^+\text{X}_2(\text{H}_2\text{O})_2$	119	16.1	4.9
136 ± 1	$\text{H}^+\text{X}_2(\text{H}_2\text{O})_3$	137	4.4	—
141 ± 1	$\text{H}^+\text{X}_3\text{H}_2\text{O}$	142	2.9	—

* Values in parentheses are corrected for dissociation (see ref. 3).

Finally, implications of the measured CH_3CN clustering equilibria will be considered. Arnold *et al.*³ have applied a steady-state treatment of the reactions converting the proton hydrates to cluster ions, containing 1, 2 and 3 X molecules, to their stratospheric ion composition data. They found that the ion family containing three X ligands is one order of magnitude less abundant than expected, assuming equal reaction rates for all three conversion steps. This was tentatively explained by a process converting the only observed ion with three CH_3CN molecules, $\text{H}^+(\text{CH}_3\text{CN})_3\text{H}_2\text{O}$, back to cluster ions containing two CH_3CN ligands. The process should be about 10 times faster than ion-ion recombination in the stratosphere around 36 km. The laboratory studies revealed that the CH_3CN molecules are less strongly bound than H_2O in the $\text{H}^+(\text{CH}_3\text{CN})_3\text{H}_2\text{O}$ complex. Therefore, two processes could be responsible for the backward conversion: thermal decomposition or ligand exchange of CH_3CN for a H_2O molecule. For the thermal dissociation, a free enthalpy value of $\Delta G \approx 13.8 \text{ kcal mol}^{-1}$ is calculated for 227 K and a gas density of $4 \times 10^{16} \text{ cm}^{-3}$ to account for the observed ion abundances, while for the ligand exchange reaction $\Delta G \approx 5.8 \text{ kcal mol}^{-1}$ is obtained for the concentration ratio $[\text{H}_2\text{O}]/[\text{X}] = 3 \times 10^6$ (ref. 3). The corresponding values derived from the laboratory measurements for the CH_3CN -containing clusters are $\Delta G \geq 12 \text{ kcal mol}^{-1}$ and $\Delta G \geq 3.6 \text{ kcal mol}^{-1}$. A thermal dissociation or ligand exchange reaction affecting the $\text{H}^+(\text{CH}_3\text{CN})_3\text{H}_2\text{O}$ ion is also observed in the laboratory studies at large $[\text{H}_2\text{O}]/[\text{CH}_3\text{CN}]$ ratios ($\gg 10^3$). We therefore conclude that the ΔG values for both processes hardly exceed the lower limits given above by a large factor, which agrees well with the findings from the atmospheric observations.

Thus the observed masses and abundances of positive stratospheric ions can be well explained by proton hydrates and $\text{H}^+(\text{CH}_3\text{CN})_i(\text{H}_2\text{O})_m$ ion clusters. The ions 136 ± 1 and 117 AMU which do not fit into this scheme might reflect the influence of a stratospheric trace gas other than acetonitrile.

Until now, no source of stratospheric acetonitrile has been known. The sharp decrease in fractional abundances of X-

Table 2 Relative comparison of hydration equilibria of laboratory and stratospheric ions

Abundance ratio	Laboratory data	Ref. 3	Ref. 4
[96]/[78]	$1.7 \times 10^{-11} [\text{H}_2\text{O}]$	2.7	5.3

containing ions above 40 km observed in rocket experiments⁸ indicates that the source of X should be at heights below about 35 km. Further ion composition measurements covering a larger height range may help locate this source and provide additional thermodynamic data on X-containing ions which can be compared with our laboratory results.

We thank Professor E. E. Ferguson for helpful discussions. Part of the project was funded by the Bundesminister für Forschung und Technologie through GSF.

Note added in proof: The kinetics of the switching reactions of proton hydrates with CH_3CN has been studied by Smith *et al.*⁹

Unusual *PT* dependence of thermal conductivity for a clathrate hydrate

R. G. Ross, P. Andersson & G. Bäckström

Department of Physics, Umeå University, S-901 87 Umeå, Sweden

Molecular clathrate solids¹ are crystals with peculiar and interesting properties. Their characteristic feature² is that one chemical species, the 'host', forms a strongly bonded structure, which encages individual molecules of a second 'guest' species. There is virtually no chemical bonding between host and guest molecules. The guests are, nevertheless, firmly constrained by high energy barriers. X-ray and neutron diffraction experiments have shown that clathrates have a periodic structure typical of crystalline solids. A clathrate hydrate² is a host substance consisting of H_2O molecules which form an ice-like, hydrogen-bonded structure. Huge geological deposits of clathrate hydrates containing natural gas are known to exist^{2,3}—these deposits may be exploitable, and in searching for clathrate hydrates knowledge of the thermal conductivity, λ , will be important. We present here a preliminary account of the first measurements of λ versus pressure (*P*) and temperature (*T*) for a clathrate hydrate. We studied a clathrate hydrate encaging molecules of tetrahydrofuran. Thermal conductivity was measured using the transient hot-wire method⁴. The accuracy of the measurements was 3% and the precision 1%. The temperature dependence was found to be unusual in that $\lambda(T)$ has a positive slope (Fig. 1), a feature never before observed with crystalline organic materials. Furthermore, when λ was measured versus *P*, it was found unexpectedly that $\lambda(P)$ was constant—behaviour never before reported for a non-metallic material.

The temperature dependence almost universally observed at $T > 100 \text{ K}$ with crystalline, non-metallic solids is $\lambda(T) \propto T^{-1}$. This negative slope agrees with the theory of phonon-phonon scattering by the simplest umklapp mechanism. Positive slopes

of $\lambda(T)$ are encountered for non-crystalline materials in the glass state. Here topological structural disorder is considered to provide the dominant phonon scattering mechanism. Disorder fixes the phonon mean free path, and the positive slope of $\lambda(T)$ is attributed to variation of the heat capacity in the well-known formula for λ due to Debye. A few inorganic crystalline solids have positive slopes of $\lambda(T)$, that is YB_{68} , KFeF_3 and FeAl_2O_4 , and structural disorder has been invoked to account for this behaviour⁵⁻⁷. Orientationally disordered plastic crystal phases⁸ are intermediate cases, showing a negative slope of $\lambda(T)$ but with much reduced steepness: $\lambda \propto T^{-0.2}$.

All non-metallic materials previously investigated exhibit a finite slope of $\lambda(P)$, usually positive, as would be expected. A few cases of negative slope have, however, recently been discovered, one being ordinary ice⁹. The magnitudes of the slopes are most conveniently compared in terms of $g = \partial \ln \lambda / \partial \ln \rho$, where ρ is the mass density. For most cases g ranges from 3 to 10, whereas for exceptional materials $g = -2.6$ (ice Ih)⁹ and $g = -6.2$ (NH_4F)^{10,11}. From the compressibility of a propane clathrate hydrate^{2,3}, on the other hand, we estimate $|g| < 0.2$, which is an order of magnitude smaller than for other substances.

The thermal conductivity of the clathrate was found to be only 15% greater than for the corresponding liquid solution. This is in qualitative agreement with the only previous measurement for a propane hydrate³. The increase in λ when going from liquid to an orientationally disordered plastic crystal phase⁸ is typically 5%, whereas a dramatic increase is usually recorded for a normal crystal¹².

Fig. 1 Isobaric variation with temperature of thermal conductivity, λ , of (tetrahydrofuran) · 17.05(H_2O) clathrate hydrate at a pressure of 0.1 GPa.

Although the tetrahydrofuran clathrate hydrate is crystalline, there is in fact some structural disorder². Recent neutron inelastic scattering results¹³ indicate reorientational motion of the guest molecules with an activation energy of ~ 0.01 eV. At temperatures of 100–300 K there would thus be frequent reorientation of the guest molecules, which might provide a phonon scattering mechanism. We propose that this dynamical structural disorder causes a dominant thermal resistivity in our clathrate hydrate. From the pressure variation of λ we conclude that the total resistive mechanism is virtually insensitive to changes in density, but we cannot yet exclude that this constancy is a combined effect of positive and negative contributions from the main scattering mechanisms.

The phase diagram for mixtures of tetrahydrofuran and H_2O versus P , T and composition is well known¹⁴. The so-called structure II clathrate hydrate exists in a very narrow region of composition. At atmospheric pressure it occurs at a composition of (tetrahydrofuran) · 17(H_2O) with congruent melting. We prepared our specimens by pouring a liquid solution of double-

distilled H_2O and spectroscopic-grade tetrahydrofuran into the Teflon measurement cell of a piston-cylinder high pressure apparatus. On decreasing the temperature at 0.01 GPa freezing occurred after 5 K of supercooling and was detected by a marked thermal arrest at 277.0 K in agreement with the phase diagram¹⁴. Such thermal behaviour during solidification excludes the possibility of glass formation. The observed discontinuity of λ at the arrest temperature corroborates the conclusion that a first-order transition was induced on cooling. Experiments were carried out at four different compositions from 16.59 to 17.55 moles of H_2O , and the variation of λ versus T and P remained the same, although the absolute values of λ differed by as much as 20% between the extreme cases. It is thus unlikely that the variation of λ reported here could have been caused by phase separation in response to changes in P and T .

It is reasonable to assume that natural-gas clathrate hydrates would behave similarly to the substance investigated here. One could thus expect λ to be small and to change little over geologically relevant ranges of temperature and pressure.

We thank Dr D. W. Davidson for suggesting this investigation and Dr G. A. Slack for useful discussion. The work was financially supported by the Swedish Natural Science Council.

Destruction of polychlorodibenzo-*p*-dioxins

D. C. Ayres

Department of Chemistry, Westfield College, Hampstead, London NW3 7ST, UK

The release of 2,4,5-trichlorophenol (2,4,5-T) containing 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) at Sèvres¹ highlighted the need for an efficient control procedure for the highly toxic² dioxin. The concomitant formation of the dioxin and the trichlorophenol during hydrolysis of *sym*-tetrachlorobenzene has led to demands for restrictions on the use of 2,4,5-T and related herbicides³. An environmental hazard is also presented by pentachlorophenol⁴ which includes the more highly chlorinated dioxins, in particular octachlorodibenzo-*p*-dioxin (OCDD). The use of polychlorophenol formulations has been banned in Sweden on the grounds⁵ that heat-stable chlorodioxins are formed during incineration; this also points to the need for degradation by chemical means. Dehalogenation of polychlorodibenzodioxins (PCDD) can be accomplished by photolysis in laboratory conditions⁶, but material adsorbed on soil is little affected⁷. Cleavage of the ether linkages with the formation of halophenols may be achieved by treatment with strong acids or quaternary ammonium salts⁸. The dibenzodioxin nucleus, is however, rather resistant to chemical attack⁹ and in the absence of a suitable control procedure the use of 2,4,5-T has been restricted in the US by the Environmental Protection Agency^{10,11}. I now report the oxidative degradation of TCDD and related compounds by ruthenium tetroxide.

Ruthenium tetroxide is a powerful oxidizing agent which reacts with a wide range of organic substances¹² including those aromatic compounds which are oxidized slowly, or not at all, by permanganate¹³. It may be safely used in solution in water or in organic solvents with no nucleophilic character, such as chloroform, nitromethane or carbon tetrachloride.

In a preliminary experiment we showed that 2,7-dichlorobenzo-*p*-dioxin (DCDD) is destroyed by ruthenium tetroxide in carbon tetrachloride solution on standing overnight at ambient temperature. The progress of this and related oxidations may be monitored by thin layer or preferably by gas chromatography, where a 2-m column of 5% OV1 on Chromosorb 750 was operated at 195 °C, with a nitrogen flow of 50 ml min⁻¹ giving a retention time of 162 s.

Subsequent work on TCDD was carried out in collaboration with J. Harrison at the Chemical Defence Establishment, Porton Down. The progress of the oxidation of TCDD ($C = 72 \mu\text{g ml}^{-1}$) at ambient temperature in carbon tetrachloride containing the tetroxide ($2 \times 10^3 \mu\text{g ml}^{-1}$, about 10 equiv.) was monitored at intervals by stopping aliquots with benzene (2 ml). Residual concentrations were determined by comparison of their electron response with that of a standard solution of TCDD ($C = 60 \mu\text{g ml}^{-1}$) with the GLC operating at 230 °C. The half life of 560 min was evaluated from the linear pseudo-first order plot of

Fig. 1 Rates of oxidation of polychlorodibenzodioxins by ruthenium tetroxide.

$\log (\text{proportion residual})^{-1}$ to time (Fig. 1). The rate of oxidation was considerably increased at higher temperatures: in carbon tetrachloride at 70 °C and with the same concentration of reagents the half life of TCDD was <15 min.

For general guidance, within this group of compounds, the temperature coefficient for the oxidation of 2,7-DCDD was determined. The rate of oxidation of this non-toxic substance at ambient temperature is similar to that of TCDD; it can therefore act as a mimic for TCDD in degradative studies. The kinetic investigation was carried out in carbon tetrachloride solution containing DCDD ($70 \mu\text{g ml}^{-1}$) and ruthenium tetroxide ($4 \times 10^3 \mu\text{g ml}^{-1}$); the results given in Table 1 were obtained from the linear plots of $\log (\text{proportion residual})^{-1}$ to time as illustrated for TCDD.

The rate constants were obtained from the half lives after the induction period from the relation $k = 1/\ln 2 \cdot t_{1/2}$. The induction period diminished progressively as the reaction temperature rose and in these examples is probably associated with a free radical process, because the formation of radical-cations from dibenzo-*p*-dioxins has been demonstrated¹⁴ and these species have also been detected¹⁵ as intermediates in other oxidations or aromatic compounds by ruthenium tetroxide.

The values for the energy of activation were calculated from the three rate constants using the Arrhenius equation giving a mean value of about 68 kJ mol⁻¹. It follows from this that the rate increase per 10 °C rise in this temperature range is about 2.4-fold.

It is possible to show that all members of the PCDD group are susceptible to attack by ruthenium tetroxide. This follows because octachlorodibenzo-*p*-dioxin (OCDD), with the most inactivating chlorine substituents, is itself degraded in refluxing

Table 1 Temperature dependence of the oxidation of DCDD⁶ ruthenium tetroxide

Temperature (°C)	Induction period (min)	Total half life (min)	t_1 after induction (min)	k (min ⁻¹)	E_{ACT} (kJ mol ⁻¹)
30	37	215	178	3.89×10^{-3}	66.65
40	10	87	77	9.00×10^{-3}	69.1
50	4	38	34	2.04×10^{-2}	

carbon tetrachloride ($C = 70 \mu\text{g ml}^{-1}$) by the oxidant ($4 \times 10^3 \mu\text{g ml}^{-1}$), with a half life of ~10 min. This result is also significant because of the possible enzymatic reduction of OCDD to dibenzodioxins of lower chlorine number: analogous changes occur¹⁶ during the metabolism of hexachlorobenzene.

We have no evidence of the nature of the fragments formed during oxidation of the polychlorodibenzodioxins. However, the related chlorophenols undergo extensive decomposition to yield chloride ions and no significant levels of organic products¹⁷.

The present work shows that ruthenium tetroxide can be used both for the detoxification of glassware and artefacts, and for the periodical purging of industrial reactors to counteract the accumulation of polychloro-*p*-dioxin residues. When using the reagent note that there is some uncertainty in the total reaction time owing to the period of induction. The induction periods given in Table 1 were, however, reasonably reproducible and the delay is not significant at the higher temperature. To obtain information about reaction kinetics the oxidant was used in excess in carbon tetrachloride, but the method is also applicable to the oxidation of PCDDs with catalytic amounts of ruthenium tetroxide as the primary reagent and regeneration by a consumable secondary oxidant, such as hypochlorite.

We thank Dr J. Harrison for DCDD and TCDD and Dr A. J. Dobbs for OCDD. This paper is Part 6 in the series 'Oxidation of Aromatic Substrates'. It was presented in part at the Chemical Society Pollution Symposium in Belfast on 26 September 1979, and subsequently in London on 1 May 1980.

A new pyroxene fractionation trend from a layered basic intrusion

J. R. Wilson*, K. H. Esbensen† & P. Thy‡

* Department of Geology, University of Aarhus, 8000 Århus C, Denmark

† Department of Metallurgy, Technical University of Denmark, Building 204, 2800 Lyngby, Denmark

‡ Nordic Volcanological Institute, University of Iceland, 101 Reykjavik, Iceland

Pyroxene fractionation trends in igneous rocks depend on the magma composition and the conditions of crystallization. Four main types of pyroxene crystallization trend have been recognized in terrestrial igneous rocks (Fig. 1). These are the clinopyroxene trend of mildly alkaline basic magmas^{1,2}; the clinopyroxene trend of strongly alkaline basic magmas³; the two-pyroxene trend typical of tholeiitic magmas⁴⁻⁶; and the two-pyroxene trend typical of calc-alkaline intrusions⁷⁻⁹. The calc-alkaline pyroxene trends show restricted iron-enrichment as high P_{H_2O} causes the crystallization of calcic amphibole (and biotite) in place of pyroxenes at a fairly early stage of fractionation. Ca-rich and Ca-poor pyroxenes from the Fongen-Hyllingen complex which coexist with hydrous mafic phases and initially have compositions very similar to those from calc-alkaline complexes, show extreme iron-enrichment in the late differentiates. This is the first recorded example of such extreme pyroxene fractionation in elevated P_{H_2O} conditions and this fractionation trend, accompanied by other distinct mineralogical features, warrants designation as a new type: the Fongen-Hyllingen trend.

The 160 km² Fongen-Hyllingen complex is an extremely differentiated basic intrusion, synorogenically emplaced in the Scandinavian Caledonides of the Trondheim region, Norway¹⁰, (11.5°E, 63°N). The complex was emplaced at a pressure of 5–6 kbar before the regional deformation and metamorphism in amphibolite facies¹¹ peaked. Sufficient primary features remain for igneous trends to be studied in considerable detail.

The complex consists dominantly of layered cumulates, of which a total thickness of ~10 km occurs in the intrusion as a whole. Cryptic layering reveals reversals to higher-temperature mineral compositions with increasing height in the cumulate stratigraphic succession, which is believed to reflect repeated magma influx¹². Despite these reversals, the highest temperature mineral assemblage in the complex occurs at the base (olivine Fo₈₆ + picotite) and the lowest temperature assemblage occurs at the top in quartz-bearing ferrosyenites (albite, hedenbergite, ferro-edenite, ilmenite, apatite, quartz, K-feldspar, zircon, biotite and allanite). These syenitic differentiates, which grade downwards into layered ferrogabbroic cumulates, occupy <3% of the exposed area of the complex. Taking the entire stratigraphic sequence, olivine spans the range Fo₈₆ to Fo₀ with a hiatus between about Fo₇₁ and Fo₆₁, and plagioclase covers the range from An₈₀ to An_{1.5}. Ca-rich pyroxenes vary from Wo₄₅En₄₄Fs₁₁ to Wo₄₇En₀Fs₅₃ and Ca-poor pyroxenes span the range Wo₂En₆₇Fs₃₁ to Wo₂En₁₇Fs₈₁. Inverted pigeonite first occurs at Fs₆₇ (calculated on a Ca-free basis) and occurs sporadically together with primary orthopyroxene at compositions more iron-rich than this. Apparently magmatic grunerite occurs instead of Ca-poor pyroxenes in the later differentiates and reaches an Mg:Fe ratio of 12:88. Magnetite and ilmenite crystallize over wide temperature intervals. Calcic amphibole is an intercumulus phase throughout most of the complex, becoming a liquidus phase in the upper parts, as well as in sporadic layers in the lower part of the cumulate succession. Its composition ranges from titanian pargasite to ferro-edenite. Biotite is a liquidus phase in the most fractionated rocks.

The coexistence of two pyroxenes, the quartz-bearing nature of the final differentiates and the 'olivine gap' broadly indicate a

tholeiitic parental magma. The detailed igneous petrology of the complex will be published elsewhere.

Broad beam microprobe analyses, ensuring reliable bulk compositions, were made of 30 Ca-rich and 20 Ca-poor pyroxenes representing the entire cumulate succession. Analyses of the most Mg-rich and Fe-rich pyroxenes are given in Table 1. While there is considerable systematic variation in the minor elements Ti, Al, Mn and Na the major trend of crystallization, represented in Fig. 1, is one of increasing Fe:Mg ratio and relatively constant Ca for both Ca-rich and Ca-poor pyroxenes.

The Fongen-Hyllingen Ca-rich pyroxene trend is close to the calcic augite-calcic ferroaugite-hedenbergite trend of the Shiant Isles sill clinopyroxenes¹, but the latter, which crystallized from a mildly alkaline basalt parent, do not coexist with Ca-poor pyroxenes. Clinopyroxenes of strongly alkaline basic magmas, such as those of the Shonkin Sag laccolith³, are enriched in Na and Fe³⁺ in the later stages and consequently their evolution, which is not ideally expressed in a En-Di-Hd-Fs diagram, bears no comparison with our pyroxenes. The Fongen-Hyllingen two pyroxene trend is very different in character from the Skærgaard solidus trend^{4,5} (augite-ferroaugite-ferrohedenbergite with coexisting bronzite-inverted pigeonite) in the calcic nature of the Ca-rich pyroxenes, the extent of Fe-enrichment of the Ca-poor pyroxenes, and the very late appearance of inverted pigeonite. However, the Fongen-Hyllingen pyroxenes are very close to the Skærgaard subsolidus pyroxene trends¹³. The latter trends are based on microprobe point analyses of individual pyroxene exsolution lamellae/hosts, while our analyses were carried out using a defocused beam (diameter ~20 µm; exsolution lamellae on the micrometre scale) to provide solidus

Table 1 Broad-beam microprobe analyses of the most Mg and Fe-rich pyroxene compositions observed in the Fongen-Hyllingen complex

Analysis no.	Ca-rich pyroxene		Ca-poor pyroxene

† Below detection limit.

compositions. This similarity is, therefore, more apparent than real and the Fongen-Hyllingen pyroxene compositions are consistent with crystallization under elevated P_{H_2O} , as indicated by the widespread occurrence of primary hydrous mafic phases.

The Fongen-Hyllingen pyroxene compositions form extensions of the calc-alkaline pyroxene trends of the Guadalupe complex^{7,8}. Guadalupe Ca-rich pyroxenes are restricted to the augite field and span the range Wo₄₃En₄₅Fs₁₂ to Wo₄₃En₃₀Fs₂₇, while the Ca-poor pyroxenes, which show no inversion from pigeonite, extend from Wo₃En₆₉Fs₂₈ to Wo₄En₃₅Fs₆₁. As a result of crystallization under fairly high P_{H_2O} in calc-alkaline complexes, the pyroxene liquidus surface is depressed, producing Ca-rich clinopyroxenes and extending the field of primary orthopyroxene crystallization to iron-rich compositions. Elevated P_{H_2O} also results in calcic amphibole being a liquidus phase at an early stage of fractionation, crystallizing together with two pyroxenes until the anhydrous pyroxenes become unstable and first Ca-rich pyroxene and then Ca-poor pyroxene cease to crystallize¹⁴. Calcic amphibole, together with biotite, then crystallize as the only mafic minerals until the end of fractionation.

Fig. 1 *a*, Pyroxene compositions from the Fongen-Hyllingen complex. *P*, first occurrence of inverted pigeonite. No inverted pigeonites have been analysed. *P* is located in the pyroxene quadrilateral on tie line between coexisting calcic ferroaugite and ferrohypersthene. *b*, Comparison of the Fongen-Hyllingen pyroxene crystallization trend with those of other igneous complexes.

The extreme pyroxene trend presented here, with highly calcic Ca-rich pyroxene reaching Mg-free hedenbergite and a very extensive Ca-poor pyroxene trend with two Ca-poor pyroxenes coexisting at Fe-rich compositions, represents crystallization under moderately elevated and increasing P_{H_2O} . Water vapour pressure was higher than that typical of tholeiitic complexes but not high enough to produce the more restricted calc-alkaline trend. Other mineralogical features, such as the wide plagioclase and olivine fractionation ranges (reaching albite and pure fayalite respectively) and the occurrence of a small volume of syenitic differentiates as opposed to large volumes of granitic material, also distinguish the Fongen-Hyllingen fractionation from calc-alkaline complexes. We propose that this new pyroxene fractionation trend be named the Fongen-Hyllingen trend.

The Danish Natural Science Research Council and the Carlsberg Foundation provided financial support to study the Fongen-Hyllingen complex.

Submarine chutes on the slopes of fjord deltas

David B. Prior & Wm J. Wiseman Jr

Coastal Studies Institute, Louisiana State University, Baton Rouge, Louisiana 70803, USA

W. R. Bryant

Department of Oceanography, Texas A and M University, College Station, Texas 77843, USA

The first side-scan sonograph images of submarine landslide chutes from arctic fjords presented here indicate that submarine slopes of fjord head deltas are subject to instability. The chutes transport sediment from the upper delta slopes into deeper water parts of the fjords. Previously, sediment distribution and budgets in the bottom of deepwater fjords were ascribed to settling of suspended sediment supplied by streams and rivers during the short summer melt period. Previous descriptions of submarine mass movements from some subarctic fjords have been limited to isolated major catastrophic events. The sonographs from an arctic fjord suggest that delta-front instability occurs as multiple small-scale events that recur at frequent intervals and are intrinsic to the fjord sedimentation system.

The underwater topography of Adventfjord, a Spitsbergen fjord, and in particular actively prograding fluvioglacial deltas and their prodelta slopes, was examined using a side-scan sonar system. Chutes or delta-front gullies were distinctive features in some locations. Although the precise origins and functions of the chutes are obscure, morphological elements suggest that they may be due to underwater landsliding or mass movement processes; however, they are undoubtedly a significant component of some fjord delta geometries and associated progradational and depositional mechanisms. The present sonographs are from a small fan delta formed by active deposition from Longyear River into the side of Adventfjord and a major delta at the head of the fjord, the result of deposition from a braided outwash stream network, Advent River.

The submarine slopes in the fjord are steep. Water depths reach 30 m very close to the shoreline. Each delta has a well-developed planar bar formed by coalescence of adjacent distributary mouth bars, which produces a relatively flat feature composed of sand, silt, and fine gravel and covered by 1–3 m of water at low tide (tidal range 1–2 m). The delta-front slopes, seawards of the bars, are steeply inclined at angles of 12–16°. At the base of the delta slopes the fjord bottom is essentially flat at water depths of 60 m. The deltas demonstrate classical slope geometry and sediment lithology with fine sands on the bars and upper slopes and grain size becoming progressively finer seaward.

Chutes were observed in the upper slopes of the deltas between 5 and 30-m water depth, that is, where bottom slope angles are greatest. Typically the chutes begin on the steepest parts of the delta on the seaward margin of constructional aprons or bars, and are not incised into the nearshore surfaces of the bars. Thus, the chutes are not simply seaward extensions of distributary channels over the top of the submerged bars, but rather originate in arcuate re-entrants, with steep head slopes, cut into the bar fronts. The chutes usually exhibit an upslope bowl-shaped source region with an upslope scarp, an elongated narrow gully section, and a downslope extensive hummocky zone.

Figure 1 shows a sonograph and interpretive map of a system of chutes radiating out from the bar front of the Longyear fan delta. The bar is extremely irregular, with some large scarped and stepped areas. The scarps occasionally seem to bound

Fig. 1 Side-scan sonograph of Longyear delta front and interpretive map.

masses that have subsided and moved seawards. A fairly continuous scarp, extending around the front of the delta, shows major re-entrants immediately above distinct chutes. The chutes begin as bowl-shaped subsidence areas but become narrower farther downslope. The subsidence areas are typically 20–25 m across, whereas the elongate chutes average 10 m in width, are incised into the delta slope to depths of 2–5 m, and have no identifiable associated levees. The chutes show two distinct tonal patterns on this sonograph. In the central part of the delta, five chutes show very dark grey tones, whereas residual interchute ridges have relatively lighter grey tones. In contrast, chutes towards the edges of the fan are lighter toned than the intervening ridges. The precise reasons for such striking tonality differences are unknown but may be due to relative age, the darker toned chutes being relatively younger with incision exposing coarser-textured delta-front deposits, the lighter toned chutes being partially infilled by fine-grained deposits settling from suspension. Figure 1 also reveals that the lower (downslope) ends of the five freshest features are marked by irregularly shaped depositional areas of blocks and spreads of dark-toned sediments.

Figure 2 shows a series of chutes on the braided outwash delta at the head of Adventfjord. Chutes again emanate from bowl-shaped source areas backed by scarps on the edge of the distal bar. The chutes are represented by lighter toned areas separated by dark-toned interchute ridges and intact platforms. They vary in width from 15 to 30 m. In some cases adjacent chutes coalesce. The incisions are relatively shallow (<3 m) where the survey line crosses the chutes. Downslope from the chutes the delta-front slope is very hummocky, with contrasting light and dark tones, indicating considerable local relief over a large area. At one place, where several chutes converge, the downslope

area consists of several subparallel blocks and scarps. Other survey data show that the chutes are present across the entire bar front and that the middle delta slope is hummocky. The hummocks, blocks, and scarps decrease in size towards the foot of the delta slope, finally merging with the flat fjord floor.

The origin of the features in Figs 1 and 2 is not precisely known. However, an attractive hypothesis is that the bowl sources, chutes, and hummocky slopes are due to submarine sediment mass movement on the actively prograding delta slopes. Mass movement (slope instability) is an important process in many other active delta environments. For example, detailed sonar mapping in the Mississippi Delta region has revealed similar mudslide gullies^{1–6}. Other examples include the Copper River delta (Alaska)⁷, the Fraser Delta (British Columbia)⁸, and the Esmeraldas and Magdalena deltas (South America)^{9,10}. There is increasing evidence of sea floor sediment mass movement specifically in subarctic fjords and glacier-fed lacustrine delta areas. For example, one classic fan delta-front failure in Howe Sound fjord (British Columbia) caused extensive damage to adjacent buildings¹¹, as did slide-generated waves in Kitimat Inlet (British Columbia)¹². A survey of the Howe Sound delta with side-scan sonar showed the presence of delta-front chutes¹³. Similarly, the geological interpretation of relict and ancient fjord deltaic sediments is relying more and more on mass movement concepts and processes¹⁴.

The combination of circumstances in fjord deltas are conducive to slope failure. Bottom slopes are steeply inclined, and rapid progradation, especially during spring melt, causes temporary oversteepening and increases gravitational stress. Rapid deposition of sands, silts, and clays can cause local excess pore pressures, especially where fine sediment layers impede pore fluid drainage. Furthermore, bar sands are built out over previously deposited fjord bottom clays and glacial flour; the latter may not be able to accept the prograding bar loads, and

Fig. 2 Side-scan sonograph of Adventfjord delta front and interpretive map.

failures may result. Finally, upfjord winds can cause surface waves, which, as they shoal over the edge of the bar, may impart significant cyclic loading effects on the bar-front sediments.

The chutes and subsidence areas on delta slopes in Spitsbergen can be interpreted as the result of avalanching or debris flow movement of the bar-front sediments. A cyclic wave-induced loading of the sediments can generate pore fluid pressures sufficient to liquefy the bar-front deposits, which are already at or near the submerged angle of repose due to normal rapid sedimentation. Similarly, locally rapid depositional oversteepening could have the same effect. The transport of sediments down the chutes transfers loading stresses to the middle slopes of the delta, which may then, in turn, suffer failure, producing irregular hummocky terrain.

As similar side-scan sonar surveys are made for other fjord deltas, it is anticipated that delta-front chutes and other results of mass movement processes may prove to be extremely common.

Foraminifera distribution of provinces in the Gulf of Mexico

Stephen J. Culver & Martin A. Buzas

Department of Paleobiology, Smithsonian Institution, Washington DC 20560, USA

Recent benthic foraminifera distribution patterns form the basis of much palaeoenvironmental (particularly palaeobathymetric) interpretation used by geologists. We have recently summarized the distribution of recent benthic foraminifera on the Atlantic continental margin of North America^{1,2} and report here the results of an analysis of all published data from the Gulf of Mexico. To obtain a synthesis of foraminiferal distribution in the Gulf of Mexico, a computerized catalogue of all published occurrences (presence or absence data) was compiled. Cluster analysis of these data isolated four large, marginally overlapping areas or provinces exhibiting a spatial correlation with Gulf of Mexico water masses. A fifth, smaller, discrete area (biofacies) was found at the mouth of the Mississippi delta.

There have been 77 papers in the past 60 years describing the distribution of recent benthic foraminifera in the Gulf of Mexico. We compiled this information using a large computer system. Our files record the distribution of 1,219 species names from 426 localities³. Through synonymization using published illustrations and specimens deposited in the US National Museum and the British Museum, the number of species was reduced to 848. Because cluster analysis of commonly occurring species on the Atlantic continental margin produced comparable results to analysis involving all species⁴, we used the 295 most commonly recorded species (those occurring at 4% or more of the 426 localities) for cluster analysis of the Gulf of Mexico data. Due to computer limitations the number of locali-

ties involved in analysis was reduced randomly to 350. The data matrix was analysed in the *Q*-mode by clustering Jaccard coefficients by the weighted pair-group method^{5–7}.

The cluster analysis produced four large, marginally overlapping areas or provinces (Fig. 1): the Coastal, Inner Shelf, Outer Shelf, and Slope and Abyssal Plain Provinces. (The diagnostic species associations of the provinces will be published elsewhere.) A fifth, smaller, discrete area or biofacies is located at the mouth of the Mississippi River.

Our analysis, based on all published presence or absence data for 295 commonly recorded species of benthic foraminifera, indicate that for the sampled littoral, inner shelf and outer shelf areas, the same foraminifera assemblages occur all around the Gulf and comprise the Gulf of Mexico Coastal, Inner Shelf and Outer Shelf Provinces respectively (Fig. 1). In deeper water, the Gulf of Mexico Slope and Abyssal Plain Province covers the whole sampled sea bed beneath depths of ~1,000 m (Fig. 1). Our circum-Gulf provinces agree with the pattern of benthic foraminifera distributions reported by Poag⁸, but he divided the deep basin into distinct eastern and western assemblages as did Dignes²⁰.

The provinces defined by our analysis seem to be unrelated to sediment substrate. For example, the Yucatan and west Florida carbonate shelves and the clastic northern Gulf of Mexico shelf east and west of the Mississippi delta are all included in the Gulf Inner Shelf Province. In agreement with macrofaunal patterns⁹, therefore, foraminifera shelf faunas on both sides of the Mississippi delta are generally the same. However, at the mouth of the delta, 10 localities group together as a discrete biofacies (Fig. 1). This group is considered to be too small and geographically restricted to be referred to as a province, but its low diversity assemblage shows close affinities to the Outer Shelf Province assemblage. The position of this biofacies is probably related to oceanographic or sedimentological conditions related to the Mississippi River discharge.

Various provincial schemes have been proposed for the Gulf of Mexico–Caribbean region using shallow water macro-invertebrates and fishes^{9–15}. The northern Gulf coast from Cape Romano, Florida to approximately the Mexico–USA border is now generally considered to be part of the east coast of North America Carolinian Province^{9,14,15}. The southern Gulf coast and the southern tip of Florida from Cape Romano to Cape Canaveral is part of the Caribbean Province, which includes the West Indian islands and the northern coast of South America^{9,14,15}. Other schemes involve greater subdivision^{10,13} or the inclusion of all the Gulf of Mexico into a Caribbean Province¹².

We compared the shallow-water benthic foraminifera assemblages from the east coast of North America south of Cape Hatteras⁴ with shallow water assemblages in the Gulf of Mexico (data unpublished). An inner continental shelf Carolinian Province, similar in extent to that defined by macro-invertebrate assemblages (see above), does not exist for benthic foraminifera. That is, inner shelf foraminifera faunas of the northern Gulf of Mexico differ considerably from those of the shelf south of Cape Hatteras. Sixty commonly recorded species are present on the east coast Southern Shelf Province, and 172 are present in the Gulf of Mexico Inner Shelf Province; only 42 species (22% of a total of 189 species) are commonly recorded species in both provinces. The question remains whether the Gulf of Mexico, based on foraminifera data, is part of a larger Caribbean Province.

A congruous relationship between foraminifera provinces and bottom water masses in the Gulf of Mexico is demonstrable. As for the Atlantic Coastal Province¹, we suggest the Gulf of Mexico Coastal Province is related to the marginal waters of bays, estuaries and lagoons. The Inner and Outer Shelf Provinces show varying amounts of overlap. The distinction between these provinces can be related to the difference in magnitude of seasonal effects between the inner and outer shelf. The critical limits of the set of environmental variables affecting the foraminifera assemblages will be located at different

Fig. 1 Recent benthic foraminifera provinces in the Gulf of Mexico; 183 m, 1,830 m, 3,660 m submarine contours are shown.

distances from the shore from year to year (or season to season); hence the considerable degree of overlap. The Inner Shelf Province on the southern margin of the Gulf may be less well defined due to sampling deficiencies or to decreased environmental variability, in particular less severe salinity changes due to a relative lack of river discharge compared with the northern margin of the Gulf.

The depth limit of seasonal effects on water mass characteristics is ~100–200 m (refs 21, 22). This depth correlates with the basinward limit of the Inner Shelf Province. Although the open surface waters of the Gulf can be divided into eastern and western parts¹⁶, the deeper water, below ~1,000–1,500 m, has generally uniform temperature, salinity and dissolved oxygen relations^{16–19}. Thus, the disposition of the pan-Gulf of Mexico Slope and Abyssal Plain Province (Fig. 1) agrees with that of the bottom water mass (that is, no division into eastern and western provinces) and an upper limit at ~1,000 m. In agreement with the provincial pattern presented here, distribution maps for Gulf of Mexico commonly recorded species³ show that all species, except one, that occur at abyssal depths range up on to the slope or even the outer shelf. Thus, there is no solely abyssal association composed of species restricted to abyssal depths.

We thank C. G. Adams, L. Isham, A. Lanham, C. McCloy, K. McCormick, D. Piacesi, D. Schnitker, D. J. Stanley, R. Cifelli and J. Whittaker for assistance. The research was supported by a Smithsonian Scholarly Studies Award.

Mimicry of antenna and photo-protective carotenoid functions by a synthetic carotenoporphyrin

René V. Bensasson*, Edward J. Land†, Ana L. Moore‡, Robert L. Crouch‡, Gary Dirks‡, Thomas A. Moore‡ & Devens Gust‡

* Laboratoire de Biophysique, INSERM U201, Muséum National d'Histoire Naturelle, 61 Rue Buffon, 75005 Paris, France

† Paterson Laboratories, Christie Hospital and Holt Radium Institute, Manchester M20 9BX, UK

‡ Department of Chemistry, Arizona State University, Tempe, Arizona 85281, USA

Carotenoid pigments, ubiquitous in photosynthetic membranes, are essential for the survival of green plants¹. Two facets of carotenoid function are recognized in photosynthetic membranes. First, carotenoids prevent the chlorophyll-photo-sensitized formation of highly destructive singlet oxygen by intercepting the chlorophyll triplet states^{2–10} and may also scavenge additional singlet oxygen present^{11,12}. Second, carotenoids perform an antenna function by transferring the energy of absorbed light at the singlet excited state level to the chlorophyll system for the execution of photosynthetic work^{13–16}. Nevertheless, the mechanisms by which carotenoids perform these functions are poorly understood. We now report that a unique synthetic carotenoporphyrin I consisting of a carotenoid part covalently linked to a synthetic tetraarylporphyrin successfully mimics both the photophysical functions of carotenoids in photosynthesis. The explanation for this seems to be the close interaction of the carotenoid and porphyrin π -electron systems.

We have previously shown that singlet-singlet energy transfer from the carotenoid moiety of carotenoporphyrin II to the porphyrin is vanishingly small¹⁷. Thus, simply placing a carotenoid in the proximity of a porphyrin is not enough to ensure antenna function. In I, on the other hand, carotenoid to porphyrin singlet-singlet energy transfer occurs with 25% efficiency¹⁸. The enhanced energy transfer efficiency in I is due to the fact that unlike II, I adopts a folded conformation in which the carotenoid π -electron system lies directly over that of the porphyrin (Fig. 1). The close approach of the two chromophores suggests that an electron exchange interaction may contribute to the observed singlet-singlet energy transfer¹⁹. In view of the fact that triplet-triplet energy transfer is necessarily mediated through exchange terms²⁰, and because singlet oxygen arises from the interaction of oxygen with a sensitizer triplet², we have investigated the photochemical and dynamic properties of the triplet states of I and II.

Singlet oxygen can be conveniently detected by spectroscopically monitoring its reaction with diphenylisobenzofuran (DPBF)²¹. In Fig. 2, singlet oxygen production detected in this manner is plotted for a variety of sensitizers including I, II, and a simple tetraarylporphyrin, III. In addition, the effect of added

carotenoids on photoproduction of singlet oxygen by III is shown. The most striking feature is the essentially complete photoprotection afforded by I when contrasted with the extensive singlet oxygen production by II. If efficient photoprotection were simply a matter of relative concentration with no specific geometric requirements, one might expect similar degrees of photoprotection in I and II. This is most definitely not the case, and an understanding of the results required a more detailed investigation of the photophysics of these systems.

Consequently, we have carried out pulse radiolysis and laser flash experiments to monitor directly the evolution of the triplet states²². The properties of the carotenoid triplet states were established by pulse radiolysis. Population of the lowest triplet states of I, II and IV by pulse radiolysis in benzene through sensitization by biphenyl²² resulted in a transient spectrum with $\lambda_{\text{max}} = 535 \text{ nm}$ and $\epsilon_T - \epsilon_G \sim 1.4 \times 10^5 \text{ M}^{-1} \text{ cm}^{-1}$, which is characteristic of a carotenoid triplet^{23,24} (ϵ_T and ϵ_G are the extinction coefficients of triplet and ground states, respectively). Similar experiments performed with III resulted in an $\epsilon_T - \epsilon_G \sim 6.8 \times 10^3 \text{ M}^{-1} \text{ cm}^{-1}$ at 440 nm, the transient difference spectrum being typical of a porphyrin. It is important to note that these transient spectra observed through pulse radiolysis for I, II and

IV are the same: the spectra and extinction coefficients for I and II are not perturbed by the covalent linkage between the two chromophores.

We now turn to the laser flash experiments. Figure 3 presents oscilloscope traces of the transient absorption changes with time for II after 353 nm laser excitation. The porphyrin triplet observed at 440 nm (Fig. 3b) appears first with $t_{\frac{1}{2}} \sim 1.5 \mu\text{s}$. Concomitant with this decay, and in a 1:1 ratio, the carotenoid triplet observed at 535 nm (Fig. 3a) rises with the same $t_{\frac{1}{2}}$. Subsequently, this absorption decays with $t_{\frac{1}{2}} \sim 7 \mu\text{s}$ (Fig. 3c). Taking into account the carotenoporphyrin concentration and the maximum possible expected intermolecular triplet energy transfer rate, this result suggests that the carotenoid is quenching the porphyrin triplet state by an intramolecular energy

Fig. 1 Idealized time average solution conformation for carotenoporphyrin I. The aromatic ring of the carotenoid moiety is $\sim 4 \text{ \AA}$ above the mean porphyrin plane. Hydrogen atoms are not shown. This conformation is based on proton NMR spectral data¹⁸.

Fig. 2 Bleaching of DPBF at 390 nm by singlet molecular oxygen. Filtered light (630 nm long pass cutoff, Oriel G-772-6300 and a water filter) from a 150-W tungsten halogen projection lamp was used to illuminate the solutions. Reactions were carried out in spectrophotometer cells open to the air at solution volumes of ~2 ml. Sample temperature was $23 \pm 1^\circ\text{C}$. All solutions were prepared from freshly distilled toluene stored over molecular sieves. All compounds were purified by TLC immediately before use except DPBF which was used as received (Sigma). The DPBF concentration was $2.1 \times 10^{-6}\text{ M}$ in all experiments. ■, $1.9 \times 10^{-6}\text{ M}$ I; ●, $1.8 \times 10^{-6}\text{ M}$ II; △, $1.9 \times 10^{-6}\text{ M}$ III plus $1.9 \times 10^{-6}\text{ M}$ β -carotene; □, $1.9 \times 10^{-6}\text{ M}$ III plus $1.9 \times 10^{-6}\text{ M}$ benzoate ester of 7'-apo-7'-(4-hydroxymethylphenyl)- β -carotene (IV); ○, $2.0 \times 10^{-6}\text{ M}$ III. The wavelength monitored (390 nm) was chosen for its relative freedom from absorbance by chromophores other than DPBF. At each point the entire absorption spectrum (200–800 nm) was acquired (Hewlett-Packard 8450 A spectrometer) to ensure that no other photochemical processes were occurring. Plotted absorbance values have been corrected by subtracting residual absorbance at 390 nm of the solution without DPBF (typically A_{390} 0.06–0.09). The initial rates (R_0) are $(A_{t_0} - A_{t_{15}})/15\text{ s}$. Illumination of $2.1 \times 10^{-6}\text{ M}$ DPBF showed the same response as I within experimental error. There was no change in absorbance at 390 nm when $2.0 \times 10^{-6}\text{ M}$ I was illuminated.

transfer process. Figure 4 presents the results for a similar experiment for I. The behaviour of this carotenoporphyrin is strikingly different. The carotenoid triplet appears immediately (Fig. 3a); the porphyrin triplet state cannot be observed even at the time resolution limit (~30 ns) of our instrument (Fig. 3b). The quantum yield, determined by the comparative method²², for the formation of the porphyrin triplet state in III was 0.45 whereas the quantum yield of carotenoid triplet state, and consequently also the yield for the formation of the porphyrin triplet state, was 0.23 in II and 0.12 in I. (These quantum yields are consistent with the increase in quenching of the porphyrin fluorescence from III to II to I^{17,18}. The competing nonradiative path from the porphyrin singlet state is of interest because electron transfer between the chromophores may be occurring. This mechanism has been proposed for the quenching of chlorophyll *a* fluorescence by β -carotene²⁵.)

From these results it is clear that the remarkable photoprotective function observed for I (see Fig. 2) is a consequence of the extremely rapid quenching of the porphyrin triplet state by the carotenoid moiety. *In vitro* studies of bacterial systems have shown that quenching of the bacteriochlorophyll triplet state by carotenoid occurs with $t_{1/2} \sim 20\text{ ns}$ (ref. 6). The difference in porphyrin triplet quenching between I and II shows that achieving the required quenching rates on the nanosecond time scale requires a conformation such as that found for I (Fig. 1), which allows a high degree of orbital overlap and therefore very strong exchange interactions. Such a conformation is not available for II.

It is interesting to speculate on the implications of the above results for the elucidation of the photoprotective and antenna functions of carotenoids *in vivo*. A stacked conformation with close approach of the π -electron systems was necessary in I both for antenna function in the singlet manifold (where energy transfer must compete with rapid internal conversion in the carotenoid)^{17,18,27} and for efficient suppression of singlet oxygen production via the triplet manifold (where porphyrin triplet quenching by the carotenoid must compete with quenching by abundant oxygen). Such a conformation was necessary because both processes require relatively strong electronic interactions between the carotenoid and porphyrin π -electron systems. Perhaps a similar arrangement of pigments, with a separation of only a few ångströms, is necessary in photosynthetic reaction centres. Indeed, results for I and II suggest that the photoprotective and antenna functions of a particular carotenoid molecule *in vivo* may involve the same chlorophyll molecule. Such intimate and specific pigment-pigment interactions are doubtless mediated by the higher-order structure of the pigment-protein complexes. Moreover, photoprotection requires a chromophore with a triplet energy below that of singlet oxygen (1 eV). Such an organic molecule must have an extensive π -electron system and will therefore strongly absorb visible light.

Fig. 3 Transient changes in absorbance of II after 353 nm laser flash. The flash was from a Q-switched, frequency tripled neodymium doped laser delivering 30 mJ with a half-peak-height pulse duration of 25 ns. The flash photolysis apparatus has been described previously²⁶. Samples were $\sim 4 \times 10^{-6}\text{ M}$ in benzene solution and were deaerated by bubbling argon. a, Carotenoid triplet absorption at 535 nm, 1 μs per div., 6.1% change in transmission (δT) per div.; b, Porphyrin triplet absorption at 440 nm, 1 μs per div., 6.8% δT per div.; c, carotenoid triplet absorption at 535 nm, 5 μs per div., 6.1% δT per div.

Fig. 4 Transient changes in absorbance of I after 353 nm laser flash. All conditions as in Fig. 3 legend. *a*, Carotenoid triplet absorption at 535 nm, 100 ns per div., 2.4% δT per div. (inset is laser pulse swept at 20 ns per div.); *b*, absorption at 440 nm, 100 ns per div., 2.8% δT per div. This change is due to depletion of the carotenoid ground state. *c*, Carotenoid triplet absorption at 535 nm, 1 μ s per div., 4.4% δT per div.; *d*, absorption at 440 nm, 1 μ s per div., 2.8% δT per div. This change is due to the repopulation of the carotenoid ground state.

The occurrence of a carotenoid-chlorophyll-protein ultra-structure which collects this light for photosynthesis while providing photoprotection is characteristic of the economy of biological systems.

Finally, biomimetic synthetic solar energy conversion systems using chlorophylls or porphyrins may well inherit problems with light-gathering efficiency and photoprotection similar to those encountered *in vivo*. As demonstrated above, carotenoid polyenes might provide a biomimetic solution to these problems.

Absence of ocular dominance patches in dark-reared cats

N. V. Swindale

Physiological Laboratory, Downing Street,
Cambridge CB2 3EG, UK

If a young monkey or kitten is monocularly deprived for a period of days or weeks, the ocular dominance stripes or patches formed in layer IV of the visual cortex by the geniculo-cortical afferents driven by that eye become smaller, while the patches formed by afferents from the other, experienced eye, spread out and increase in size^{1,2}. One explanation for this effect is that it results from a disturbance of a competitive process which, during the first weeks of life, guides a 'sorting out' of the initially intermixed right and left eye inputs into complementary, largely non-overlapping territories^{1,3}. One feature of this process may be a local interaction between right and left eye synapses in which like synapses reinforce each other's growth rates and cause rejection of the other eye's synapses^{1,4}. If this is the case, then the effect of monocular deprivation on the relative sizes of the two sets of columns can be explained by supposing that the strengths of the effects exerted by the deprived eye are reduced^{1,4}. This explanation has a testable consequence: if both eyes are deprived of vision then each eye should be made less effective in eliminating the other eye's inputs, and the overall rate at which the ocular dominance columns form should be decreased⁴. Although LeVay *et al.*⁵ found that columns were present in a 7-week old monkey reared in the dark from the age of 3 days, this result does not necessarily imply that the rate of column formation had been normal, because in normal monkeys the columns are well developed by 3 or more weeks of age⁵. I report here the results of transneuronal autoradiography in cats, which show that columns, as revealed anatomically, are undetectable in most parts of the visual cortex of cats reared in the dark for periods of up to 20 weeks, implying that visual experience is necessary for their proper formation.

Six kittens were used; four were reared in complete darkness and studied at the ages of 8, 10, 16 and 20 weeks, while two normal kittens of 8 and 10 weeks of age served as controls. Each animal had its right eye injected, under Halothane anaesthesia, with 2 mCi of ³H-proline dissolved in 100 μ l of saline. They survived a further 12-14 days, after which they were given a lethal dose of barbiturate and perfused with 4% paraformaldehyde in 0.1 M phosphate buffer. Frozen sections 30 μ m thick were cut in a horizontal plane through the visual cortex, mounted on gelatin-coated slides, defatted and dipped in Ilford K2 emulsion diluted 1:3 with 1% glycerol⁶. After exposure periods of 2 weeks to 2 months, the slides were developed in D19 (Kodak), fixed in hypo, and coverslipped without counterstaining.

Table 1 Degree of spillover in the lateral geniculate nuclei ipsilateral and contralateral to the injected eye

Age (weeks)	Right (ipsi)	Left (contra)
8 } Normal	16%	26%
10 } Normal	*	*
8 } Dark-reared	9%	21%
10 } Dark-reared	9%	17%
16 } Dark-reared	*	*
20 } Dark-reared	23%	12%

The table shows the degree of spillover in the lateral geniculate nuclei ipsilateral and contralateral to the injected eye (which was always on the right side) of the normal and experimental animals. The amount of label present in the lamina (A or A1) not innervated by the injected eye is expressed as a percentage of that in the lamina which was innervated. There is no suggestion that spillover is more severe in the dark-reared animals.

* Data unavailable.

As spillover of radioactive label into geniculate laminae not innervated by the injected eye has been shown to lead to an underestimate of the degree of segregation of the two eyes' terminals in the visual cortex³, I also examined the effect of dark rearing on this. The procedure was similar to that of LeVay *et al.*³: 1- μ m Araldite sections of the lateral geniculate nucleus were cut, coated with emulsion and processed in the same way as the frozen sections. Grain counts were made in laminae A and A1, which are innervated by the contralateral and ipsilateral eyes respectively, and the ratio of the two values expressed as a percentage (Table 1). No systematic differences between dark-reared and normal animals were found, although spillover was usually more severe on the contralateral side³.

The labelling pattern in both the 8- and 10-week old normal animals studied was similar to that found in normal adult animals^{3,7} (Fig. 1). In layer IV of area 17, ipsilateral to the injected eye, the label formed patches 200–600 μ m wide, spaced at roughly 800- μ m intervals, with a level of label in the gaps between which was only slightly higher than the background in adjacent layers of the cortex. In area 17 contralateral to the injected eye, the label was also distributed periodically, although the level of label in the gaps between the columns was higher than on the ipsilateral side. This probably results from the greater degree of spillover on this side.

All four dark-reared animals gave similar results. Over most of area 17, on sides both ipsilateral and contralateral to the injected eye, the distribution of label was almost uniform (Fig. 2), although in some parts of the cortex, slight fluctuations, whose periodicity was not obviously abnormal, were present. The level of label in the troughs of these fluctuations was always much higher than in the gaps between the labelled columns in the corresponding hemispheres of normal animals. They were always more pronounced in the ipsilateral hemisphere and were less noticeable or absent in regions of cortex receiving inputs

Fig. 2 Autoradiographs from the left and right hemispheres of an 8-week old dark-reared kitten, whose right eye was injected. The distribution of label is nearly uniform in both hemispheres.

Fig. 1 Dark field autoradiographs from single horizontal sections through the left and right visual cortices of an 8-week old normal kitten whose right eye was injected with radioactive label. The label has a periodic, patchy distribution in layer IV of both hemispheres. In this and Fig. 2, the left hemisphere is on the left-hand side, and anterior is uppermost. Scale bar, 1 mm.

from peripheral retina. Contrary to expectation they were, if anything, less noticeable in the older dark-reared animals.

Although these results show that total visual deprivation interferes substantially with the process by which left and right eye terminals segregate to form ocular dominance columns, it remains unclear whether the deprivation is, as predicted, simply slowing the rate of segregation, in which case the columns should form eventually, or whether the process halts or even reverses after an intermediate stage of development. Some degree of development has occurred in the dark, because the fluctuations found in some parts of the cortex are absent from normal 2-week old animals³ (despite their several days' visual experience). The dissimilarity between these results from cats and those from the 7-week old dark-reared monkey studied by LeVay *et al.*⁵, which possessed an apparently normal set of ocular dominance columns, is also puzzling, but more experimental work is needed to clarify the nature of the difference.

Cats reared in the dark for four or more months are known to be abnormally sensitive to the effects of monocular deprivation, judged by changes in the responsiveness of cortical cells to visual stimuli⁸. This is at a time when similar deprivation would be without effect in a normal animal. The present results therefore support the idea that the critical period for monocular deprivation is linked to the time when left and right eye inputs to the cortex are incompletely segregated^{1,3,4}.

I thank Lyn Cummings for technical assistance and Ralph Freeman for helpful discussions. The research was supported by grants to Professor H. B. Barlow from the MRC and the Royal Society.

Common precursor of lysozymes of hen egg-white and bacteriophage T4

B. W. Matthews, M. G. Grütter, W. F. Anderson* & S. J. Remington*

Institute of Molecular Biology and Department of Physics,
University of Oregon, Eugene, Oregon 97403, USA

The lysozymes of hen egg-white and bacteriophage T4 have similar catalytic properties but their amino acid sequences are not homologous. The question therefore arises whether they are derived from a common ancestral protein or have arisen independently. On the basis of the data we have gathered, it is shown here that the two enzymes are similar in the conformation of their backbones, in their modes of binding substrates, in specific protein-substrate interactions and in their presumed modes of action. We conclude that the two enzymes have diverged from a common precursor. This seems to be the most convincing example to date of the divergence of proteins with nonhomologous amino acid sequences.

If anything, the large number of protein structures and amino acid sequences now known has confused rather than simplified the main issue of whether extant proteins have evolved from a small number of ancestral precursors or have arisen independently. When the amino acid sequences are closely homologous, there is no difficulty: three-dimensional structures are always similar, and it is reasonable to infer that there is a common ancestral protein. In the absence of sequence homology, on the other hand, the origin of two proteins is logically ambiguous. Functional and/or structural similarity may indicate either divergent evolution from a common precursor or convergent evolution from amino acid sequences arising independently.

In many circumstances, tell-tale sequence homology is not readily apparent. The most notable example is the 'nucleotide-binding domain' of four NAD-dependent dehydrogenases and certain other enzymes¹⁻⁵. Although the amino acid sequences of lactate, alcohol and glyceraldehyde-3-phosphate dehydrogenases are not obviously homologous, when the sequences are aligned in such a way that common structural features coincide, a degree of sequence homology becomes evident, suggesting divergent evolution. In other cases of enzymes with similar structures but no apparent sequence homology, the question of divergent or convergent evolution has remained open⁶⁻²¹. The greater the structural correspondence between two proteins, as estimated by a variety of methods^{4,16,22-28}, the more likely are the two proteins to have evolved from the same precursor, but structural similarity *per se* is no proof of divergence. In some instances, two domains of a single protein have been observed to have structural similarity but not sequence homology. The fact that the polypeptide chains of the two domains are contiguous, even though their sequences are not related, has been taken as evidence for gene duplication, that is, a special case of divergent evolution^{9,28-30}.

In the case of bacteriophage T4 lysozyme (T4L) and hen egg-white lysozyme (HEWL), there are additional critical features common to the respective structures which strongly suggest that the two enzymes have diverged from a common precursor. Correspondence between HEWL and T4L can be seen at three levels: (1) the respective backbones, (2) the locations of saccharides bound in the respective active site clefts and (3) specific protein-substrate interactions and the probable mechanisms of catalysis.

Rossmann and Argos⁴ showed that, allowing for certain insertions and deletions, the amino-terminal half of T4L is structurally similar to HEWL. Of the 129 residues in HEWL and 164 in T4L, 78 α -carbon atoms were found to be 'equivalent' and could be superimposed within a r.m.s. distance of 4.1 Å. Notwithstanding the structural correspondence, the minimum base change per codon for the 78 'equivalent' residues is 1.53, a value expected for two amino acid sequences chosen at random. Remington and Matthews²⁵ used a different method of comparing the two lysozyme structures and concluded that the agreement between them was significantly better than one would expect by chance. The part of T4L 'equivalent' to HEWL is shown in Fig. 1.

Recently, we have completed a study of the binding of a series of mono- and oligosaccharides to phage lysozyme which has permitted a detailed comparison of the respective active sites of T4L and HEWL^{31,32}. We took the coordinates of the tetrasaccharide δ -lactone bound to HEWL³¹, and, using the respective transformations between HEWL and T4L proposed by Rossmann and Argos⁴ and Remington and Matthews²⁵, transformed these coordinates into the T4L coordinate frame. As summarized in Table 1, the centres of the four sugars agree within 1–2 Å with the saccharide binding sites determined experimentally for T4L. The experimental data provide striking confirmation of the sugar binding sites in T4L predicted by Rossmann and Argos, and support their conclusions concerning the relationship between the two lysozymes. Furthermore, there is remarkable agreement (Fig. 2) between parts of T4L and HEWL which are critically important for substrate binding and catalysis.

In the case of HEWL, Phillips and co-workers proposed a mechanism of action in which substrate strain in subsite D favours the formation of a carbonium ion intermediate which is stabilized by Asp 52, with Glu 35 acting as the proton donor^{33,34}. Subsequent work suggests that electronic stabilization rather than strain may be more important in promoting catalysis^{35,36}. In the case of T4L, we see a close parallel^{31,32}. Here, model building suggests that, as with HEWL, a saccharide with the normal chair conformation cannot be accommodated in site D because of steric interference, but a saccharide in the sofa conformation, as in the proposed transition state, will fit into the D site. For HEWL, the critical close contact in site D is between C₆₆ and the backbone C=O of Gln 57. As can be seen in Fig. 2, an exactly analogous close approach occurs for T4L between C₆₆ and the backbone C=O of Gly 30. In addition, for both enzymes the NH of the adjacent peptide forms a characteristic hydrogen bond to the acetamido group of saccharide C which is thought to help promote the preferential binding of monosaccharides in site C.

Finally, Asp 20 of T4L is in virtually the identical position, relative to substrate, as Asp 52, and is ideally placed to stabilize the developing positive charge on the postulated carbonium ion intermediate. Glu 11 of T4L is close to, but not in exactly the same relative position, as Glu 35 of HEWL, and is salt linked to Arg 45, in contrast to the nonpolar environment of Glu 35. Assuming a slight conformational adjustment when substrate is bound, Glu 11 could move into the required position to act as

Table 1 Comparison of predicted and observed saccharide binding sites for phage lysozyme

Saccharide subsite	Distance between predicted and observed site (Å)	
	Prediction based on 78 'equivalent' α -carbon atoms ^{4,32}	Prediction based on the best agreement between 80 contiguous α -carbon atoms ^{25,32}
A	1.8	2.6
B	1.5	1.6
C	1.5	1.1
D	1.5	1.2

* Present addresses: Department of Biochemistry, University of Alberta, Edmonton, Alberta, Canada T6G 2H7 (W.F.A.); Max-Planck-Institut für Biochemie, D-8033 Martinsried bei München, FRG (S.J.R.).

Fig. 1 Stereo view of the α -carbon backbone of bacteriophage T4 lysozyme showing the location of a bound oligosaccharide. The solid lines connect the 78 α -carbon atoms of phage lysozyme which have equivalent α -carbons in hen egg-white lysozyme⁴.

Fig. 2 Superposition of elements of the active site of hen egg-white lysozyme (open bonds), including a bound tetrasaccharide, on the corresponding elements of T4 phage lysozyme (solid bonds and names underlined).

the proton donor, as Glu 35 is postulated to do in HEWL. (Additional details are given in ref. 32.)

Thus, phage lysozyme and HEWL have similarities in their backbone conformations, in the locations of bound substrates and in the specific details of substrate binding and catalysis. These similarities strongly suggest that the two lysozymes have diverged from a common precursor. To argue for convergent, rather than divergent evolution, one would have to postulate that the similarities between the two lysozymes which we have enumerated all arose independently. We consider this unlikely.

The two lysozymes provide an example of the changes in proteins which can occur during evolution. In this case the only amino acids which seem to have retained their identities are Glu 11 (Glu 35) and Asp 20 (Asp 52). Other similarities between the respective lysozymes (Figs 1, 2) are at the level of the protein backbone rather than side-chain identity. As will be described in more detail elsewhere, the part of the upper lobe of T4L (Fig. 1), which has no counterpart in HEWL, seems to be involved in binding the cross-linking peptide of *Escherichia coli* cell walls. This peptide is required for substrates of T4L, but is not essential for HEWL.

After the submission of this manuscript, Jung *et al.*³⁷ reported the locations of the four exons of HEWL. Exon 2 codes for amino acids 28–32 and exon 3 for amino acids 82–108. Taken together, these two regions include the part of HEWL which is most similar to T4L and support the hypothesis³⁸ that exons may have been involved in the evolution of proteins. The same suggestion has been made independently by P. J. Artymiuk, C. F. Blake and A. E. Sippel (personal communication).

‡ Frederick Cancer Center, Frederick, Maryland 21701, USA

An outbreak of horizontally transmitted malignant lymphoma in an experimental hamster holding facility was previously reported¹. Retroviridae (oncornavirus) or other conventional oncogenic viruses (oncoviruses) could not be detected in these lymphomas by immunological methods, direct isolation procedures or electron microscopy² but an infectious agent was clearly involved. The incidence of lymphomas during five recurrent epidemics ranged from 50 to >90% in young, inbred and random-bred Syrian golden hamsters exposed¹. The agent seemed to be resistant to UV inactivation, formaldehyde vapour and other viricidal agents (chlorine and iodine), and stable for long periods in the absence of hamster hosts in the contaminated facility^{1,2}. Associated disease syndromes in exposed hamsters included severe enteritis, pyelonephritis, the occasional appearance of warts, poor breeding efficiency and intussusception^{1,2}. We now report the successful, cell-free isolation of an unusual, filterable agent prepared in protamine sulphate buffer from primary and animal-passaged lymphomas, which produces lymphomas with good efficiency when injected subcutaneously (s.c.) into newborn Syrian inbred (LSH) and random-bred (LVG) hamsters. The agent could be reisolated from these induced lymphomas and injected into other hamsters to reproduce the neoplastic condition. It showed characteristics suggested for a mammalian viroid (a non-encapsidated, DNase-sensitive low-molecular-weight, disease-causing, self-replicating, naturally infectious nucleic acid).

Various isolation techniques³⁻⁶ were used in attempts to obtain cell-free, filterable agent responsible for lymphoma induction in young or newborn hamsters inoculated either s.c. or intraperitoneally (i.p.) (Table 1). None of these yielded cell-free oncogenic agent, but the incidence of 'background' lymphoma mediated by naturally transmitting agent among the hamsters housed in the contaminated facility was suppressed in hamsters challenged with non-oncogenic extracts of lymphoma, compared with placebo controls which received buffer or normal spleen extracts. In this report, data are given for the incidence of background lymphomas detected among control or test hamsters placed in the agent-contaminated facility. The incidence of background lymphomas can range from 0 to >50% in some rooms. Such spontaneous lymphomas contracted from agent in the facility were unavoidable because we could not use new facilities for each experiment. Previous work demonstrated that it was difficult to rid the unit of contaminating agent by extensive sanitization that would destroy most viruses. However, background lymphomas were readily discerned from protamine sulphate (PS)-stabilized agent induced tumours by site of appearance.

We obtained cell-free agent using a simple extraction method in which PS (0.01 mg ml⁻¹) was added to the extraction buffer (Fig. 1). Filtered (0.45–0.1 µm) extracts of lymphoma prepared with PS were able to produce 40–95% lymphomas in trials carried out over 2 yr when inoculated s.c. into newborn hamsters. Two additional PS preparations were tested s.c. in newborns in a new facility which was free of contamination and

Table 1 Protection of hamsters against contagious lymphoma after injection of Moloney extracts of spontaneous intestinal lymphoma

Preparation	Hamsters with lymphomas/ Test extract (%)	Control buffer solution (%)
Moloney extract:		
Trial 1	4/18 (22)	9/9 (100)
Trial 2	0/16 (0)	4/11 (36)
Trial 3	2/34 (6)	3/9 (33)
Freeze-thaw extract	3/34 (9)	4/9 (44)
Saline homogenate	1/11 (10)	3/9 (33)
Phenol extraction*		
Trial 1	0/20	0/4
Trial 2	0/30	0/7
Trial 3	0/37	NT
Hirt extraction*		
Trial 1	0/10	2/10 (20)
Trial 2	0/23	1/9 (11)

The Moloney extract comprised 15 g of lymphoma extracted in citrate buffer and hyaluronidase (for methods see Fig. 1 legend). 0.5 ml was injected into the right rear legs of 3–4-week-old LVG hamsters. All solutions were passed through a 0.45-µm filter. All lymphomas recorded were at node sites in the peritoneal cavity or in the cervical-thymic node area. The freeze-thaw extract comprised 15 g of lymphoma extracted after three repetitive flash freezes (–80 °C) and slow thaw (25 °C) in phosphate-buffered saline (PBS), pH 6.8. The solution was passed through a 0.45-µm filter and 0.05 ml injected i.p. The saline homogenate comprised 15 g of lymphoma extracted by homogenization in PBS and filtered through a 0.45-µm membrane. 0.05 ml was injected i.p. Each group originally comprised 40–48 newborns. The survivors were rapidly reduced to those given by enteritis. Young hamsters which died from enteritis had no lymphomas at the time of death (2–6 weeks). Enteritis was not seen after 5–6 weeks, and was observed equally in control groups and in hamsters injected with lymphoma extracts. These trials were carried out in a new trailer unit. NT, not tested.

*Lymphomas in these groups were detected in the lower flank, adjacent to the injection site.

were oncogenic. These tumour preparations were from cell-free, PS agent induced lymphomas. When the same PS-stabilized extracts were injected i.p., there were fewer tumours in the injection area than after s.c. injection (data not shown).

Electron microscopy using several staining methods^{7,8} on spontaneous lymphomas, animal-passaged lymphomas and concentrated PS extracts of lymphoma oncogenic in newborn hamsters were devoid of virions unique to the lymphomas. R or H particles and rare budding particles were infrequently observed in normal and fibroblastic tissue and epithelial cells from lymphomatous hamsters, but these were also commonly detected in non-exposed hamsters⁹ from breeder sources. We concluded that there were no virions or virus-like particles (VLPs) unique to lymphoma tissue or to uninvolved hair follicles, skin, spleen, gut, or normal lymphocytes of lymphoma-bearing hamsters.

Preparations of lymphoma or serum from lymphoma-bearing hamsters were tested for mycoplasma, antibody to lymphocytic choriomeningitis virus, SV40, polyoma and SV5 and Reo virus, with negative results. Antibody to Sendai virus was present in healthy, breeder-supplied hamsters. In repeated trials, serum from either lymphoma-bearing or their exposed, disease-free cage-mates failed consistently to neutralize PS-stabilized agent and prevent lymphoma induction.

Hamster age was most important in maximum sensitivity to s.c. oncogenic challenge with PS-stabilized, filtered extracts of lymphoma (Table 2), with 1-day-old, but not 10-day-old, hamsters being most susceptible. The oncogenic agent in PS was readily inactivated by DNase but not by RNase or proteases (Table 3).

Diener¹⁰ concluded that a viroid etiology should be considered when: (1) no microorganism was consistently associated with the disease; (2) VLPs could not be identified in extracts or sections of diseased tissue by electron microscopy; (3) the

infectious agent was difficult to pellet by ultracentrifugation; and (4) nuclease treatment inactivated the agent. Fulfilment of these criteria alone does not constitute absolute proof of a viroid aetiology which depends on demonstrating non-encapsidated nucleic acid¹⁰.

We suggest that this lymphoma agent is a naturally transmitting, oncogenic, naked DNA viroid-like agent whose origin and mode of transmission remain unclear. The agent is difficult to sediment in buffer, DNase labile, produces no unique virus particles in lymphoma tissue or normal tissues of the tumour-bearing host nor in concentrated, filtered oncogenic extracts, and requires PS for cell-free stabilization. It seems to be unrelated to known oncogenic Retroviridae or papovaviruses, and generates no neutralizing antibody in trials using tumour-bearer or disease-free cage-mate serum. We must still prove the existence of infectious nucleic acid to claim a viroid status for the oncogenic agent.

Graffi *et al.*¹¹⁻¹³ reported a similar disease in Syrian hamsters and attributed the cause to an unidentified budding virus of the Retroviridae family. They suggested that various agents, such as

Fig. 1 Lymphoma production using extracts of hamster lymphoma. ○, Control (no inoculations). Hamsters inoculated s.c. in rear flank: ▲, Moloney method; ■, PS method (LSH recipients); ●, PS method (LVG recipients); △, control (Moloney extraction buffer only); □, control (PS solution only). Modified Moloney extraction method: a 6.6% suspension was prepared of intestinal lymphoma which had been finely minced in 0.153 M potassium citrate containing 1 mg of hyaluronidase per 100 ml. This was digested for 1 h at 25 °C with occasional mixing in a blender (15-s pulse) and homogenized in the blender in an ice bath (3 min). The extract was centrifuged at 2,500 r.p.m. for 20 min at 4 °C and the middle supernatant (S_1) collected. This was centrifuged again as above and the middle supernatant (S_2) collected. S_2 was centrifuged at 17,000g for 1 min at 4 °C and the supernatant (S_3) collected. S_3 was filtered through a 8- μ m Biorad filter, then through a 1- μ m Biorad filter, and finally a 0.45- μ m Millipore filter. The S_3 filtrate was centrifuged at 40,000g for 1 h at 4 °C and the pellet rinsed three times with 0.05 M sodium citrate buffer, pH 6.7. The pellet was resuspended in citrate buffer using 1 ml per g of original lymphoma and exposed to three 1-s bursts with a sonicator to achieve cavitation. 0.1 ml was injected s.c. Protamine sulphate method: lymphoma (10–15 g) was minced to a fine suspension in Hank's balanced salt solution, and the final suspension forced through an 18-gauge needle. The cells were pelleted at 1,500 r.p.m. for 10 min at 4 °C and the pellet washed twice with 5 ml PBS, pH 6.8, per 5 g tumour used. The pellet was resuspended in PBS containing 0.01 mg ml⁻¹ PS, 0.01 M Tris, 0.001 M EDTA (pH 8.0) and kept at 4 °C for 30 min. This was homogenized in a Dounce unit and centrifuged at 2,000 r.p.m. for 10 min at 4 °C. The supernatant (S_1) was centrifuged in a 50 Ti Beckman rotor at 10,000g ($\omega^2 t = 365$) for 60 min at 4 °C. The supernatant (S_2) was filtered through a 0.45- μ m Millipore filter, then a 0.22- μ m filter. 0.1 ml was injected s.c.

Table 2 Relationship of age to susceptibility to lymphoma induction by cell-free, filtered preparations from spontaneous lymphoma

Protamine extract of:	Age of challenge (days post-birth)	Final tumour incidence (tumours/survivors, %)
Normal hamster spleen	1	2/17 (12)
	5	1/12 (8)
	10	3/22 (9)
Buffer alone	1	3/23 (13)
	5	0/11 (0)
	10	2/20 (10)
Spontaneous lymphoma	1	14/20 (70) $P < 0.01^*$
	5	9/22 (41) $P < 0.05$
	10	5/24 (21) $P > 0.05$ NS

A spontaneous lymphoma which appeared in the lymph node of the neck area (weight 5.3 g) was removed and extracted using the PS extraction method (see Fig. 1 legend). 0.05 ml of the final supernatant was injected s.c. into the lower rear quadrant of hamsters. Hamsters were challenged with extracts on the day indicated. All mothers were obtained from the Charles River Hamstery as primiparous and all groups were weaned and sex segregated at 21 days of age. Hamsters were palpated and examined weekly for evidence of tumour. The experiments were terminated at 222 days after birth and survivors autopsied for evidence of tumours. The last tumour was detected at 178 days and the first appeared at 28 days. NS, not significant.

* Significance by χ^2 compared with normal spleen cell extract.

Table 3 Susceptibility of oncogenic agent-producing lymphomas to DNase

Treatment	Cumulative no. lymphomas/ no. survivors Days post-injection of neonate LVG hamsters			
	0	80	100	150
None—filtered PS-stabilized lymphoma extract alone (30 min, 37 °C)	0/17	4/9	7/9	8/9
DNase (30 min, 37 °C) plus filtered PS-stabilized lymphoma extract	0/20	0/16	0/16	0/15
Trypsin (0.25%; 20 min, 37 °C) plus filtered PS-stabilized lymphoma extract	0/16	8/16	16/16	—
RNase (30 min, 37 °C) plus filtered PS-stabilized lymphoma extract	0/10	3/9	4/6	6/6
Heat-inactivated DNase* (30 min, 37 °C) plus filtered PS-stabilized lymphoma extract	0/13	3/12	8/9	9/9
Control—PS-containing extraction solution only (no tumour)	0/15	0/14	1/14	1/14

DNase, deoxyribonuclease 1, type 1, bovine pancreas (Sigma); RNase free, 250 μ g ml⁻¹. As little as 50 μ g ml⁻¹ gave the same result in another trial. Trypsin, type IX (Sigma), 0.5%. Papain was also ineffective in another trial. RNase, ribonuclease, type A-1, protease free (Sigma).

* DNase was inactivated by boiling for 10 min before use.

human tumour DNA and hamster papilloma DNA, could activate an endogenous C-type virus which induced the lymphomas observed. We find no evidence for such a retrovirus in our epidemic disease. M. Gardner (personal communication) found that saline could activate lymphoma in Graffi's hamster stock; therefore it is possible that an agent identical to the one described here was being transmitted unrecognized in the Graffi hamster.

There are several problems in resolving the nucleic acid nature of this lymphoma-inducing agent: (1) it is highly stable in the environment (facility contamination); (2) the bioassay used

to detect the agent is long-term and expensive; (3) agent-producing cell cultures of the lymphoma have not been obtained despite extensive culture efforts—cells fail to grow *in vitro*; (4) reliable *in vitro* transformation of target cells by the agent has not been detected; (5) antigenic markers for the agent on transformed lymphoma cells are not yet sufficiently developed; and (6) other potential mammalian hosts are not susceptible to the agent. Work is being done to characterize this infectious, oncogenic DNA agent.

We thank Dr T. O. Diener for helpful comments during preparation of the manuscript. This work was supported by NCI grant CA 23491, NIH.

$(\text{Na}^+ + \text{K}^+)\text{ATPase}$ has one functioning phosphorylation site per α subunit

W. H. M. Peters, H. G. P. Swarts,
J. J. H. M. de Pont,
F. M. A. H. Schuurmans Stekhoven
& S. L. Bonting

Department of Biochemistry, University of Nijmegen, PO Box 9101, 6500 HB Nijmegen, The Netherlands

$(\text{Na}^+ + \text{K}^+)\text{ATPase}$ contains two different subunits, a catalytic subunit (α) and a subunit with uncertain function (β). The enzyme binds ATP, ouabain and vanadate, and can be phosphorylated by ATP as well as by inorganic phosphate. From the previously reported maximal binding and phosphorylation capacities of 3.5–4.3 nmol P per mg protein^{1–3} (based on Lowry protein determination) and the earlier molecular weight value of ~250,000^{1,2}, a molar binding and phosphorylation capacity of 0.87–1.07 mol per mol enzyme was derived. As it is generally agreed that the enzyme molecule contains two α subunits^{1–6} or even a multiple of two^{7,8}, it has been suggested that the enzyme operates by means of a so-called 'half-of-the-sites mechanism', whereby only one of the two α subunits can be phosphorylated at any one time^{9,10}. We now present evidence that every α subunit can be phosphorylated simultaneously, which rules out the operation of such a mechanism.

We have recently shown that the molar ratio of the α and β subunits in the enzyme from the rabbit kidney is 1:1 (ref. 11). We have also determined the molecular weights of the subunits by sedimentation equilibrium analysis in the absence of detergent. After correction for carbohydrate and residual phospholipid contents, we obtained protein molecular weights of 120,600 for the α subunit and 42,800 for the β subunit. This means that the smallest unit, containing the catalytic subunit,

would be an $\alpha\beta$ dimer with a protein molecular weight of 163,400.

During these studies we noticed considerable discrepancy between results of the commonly used modified Lowry method¹² with bovine serum albumin as a standard and the absolute method by means of quantitative amino acid analysis. Recently, Craig and Kyte⁶ have also indicated that the Lowry method may give falsely high results for this type of membrane protein. We have, therefore, compared the Lowry protein values for a number of $(\text{Na}^+ + \text{K}^+)\text{ATPase}$ preparations with those from the absolute method of quantitative amino acid analysis in the presence of an internal standard (Table 1). The protein values obtained with the Lowry method are 1.345 (s.e.m. 0.018, $n = 6$) times greater than those obtained with the absolute method.

This finding has far-reaching consequences for several parameters of $(\text{Na}^+ + \text{K}^+)\text{ATPase}$, such as its turnover number and specific activity, and especially its phosphorylation capacity. Nearly all published values for these parameters are based on Lowry protein determinations according to the original procedure¹³ or to modifications of this method; it would now seem that these values are generally too low.

We have also reinvestigated the phosphorylation capacity and found that the removal of endogenous ATP, which is added during purification of the enzyme to stabilize it, lowers the specific activity by 21% (s.e.m. 6, $n = 11$). We have, therefore, determined the phosphorylation capacity both with and without prior removal of endogenous ATP. Results, plotted as phosphorylation capacity against specific activity for a given preparation, are shown in Fig. 1, with technical details in the legend. A linear relationship between these two parameters is found, with the values obtained with or without removal of ATP before phosphorylation falling along the same line. For the most active preparations a phosphorylation capacity of 5.6 nmol P per mg protein (based on amino acid analysis) is obtained, slightly

Fig. 1 Relationship between phosphorylation capacity and specific activity of 41 purified $(\text{Na}^+ + \text{K}^+)\text{ATPase}$ preparations from rabbit kidney. The enzyme was prepared as previously described¹². Activity was determined according to Schoot *et al.*¹⁵ and protein by quantitative amino acid analysis as described in Table 1 legend. Phosphorylation was carried out as described before¹⁶ (34 preparations) or with the modification that the enzyme is phosphorylated without prior removal of endogenous ATP (seven preparations). In the latter case excess $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ (1–2.5 mM, diluted with cold ATP) was added. In both cases there is the same linear relationship between phosphorylation level and specific activity of $(\text{Na}^+ + \text{K}^+)\text{ATPase}$. The equation for the regression line, calculated by the method of least squares, is $y = 1.737 \cdot 10^{-3} x + 0.219$ ($r = 0.90$).

Table 1 Protein content of rabbit kidney ($\text{Na}^+ + \text{K}^+$)ATPase determined by the Lowry method and by amino acid analysis

Preparation no.	Lowry method (mg protein ml ⁻¹)	Amino acid analysis (a.a.a.)	Ratio Lowry/a.a.a.
1	4.80	3.67	1.308
2	1.52	1.14	1.333
3	2.01	1.47	1.367
4	2.03	1.48	1.372
5	1.67	1.19	1.403
6	2.05	1.59	1.289
Mean			1.345 ± 0.018 (s.e.m.)

A 100- μl aliquot of a ($\text{Na}^+ + \text{K}^+$)ATPase suspension (~ 2 mg protein ml⁻¹) in 0.25 M sucrose, 10 mM Tris-HCl, 1 mM EDTA (pH 7.4) was added to a glass tube containing 150 nmol norleucine, followed by 300 μl 7.6 M HCl. The tube was vacuum sealed and hydrolysed in the dark for 24 h at 105 °C. After 10 min centrifugation at 20,000g, amino acid analysis of the supernatant was carried out in a modified JEOL type JLC-6AH amino acid analyser. The results of the amino acid analysis were corrected for incomplete hydrolysis of valine and isoleucine and degradation of serine and tryptophan¹¹. The protein content was calculated by summation of the amino acid weights. Parallel samples of the ($\text{Na}^+ + \text{K}^+$)ATPase suspension were analysed for protein according to Lowry *et al.*¹³ after trichloroacetic acid precipitation as described by Jørgensen¹².

higher than the recently reported¹⁴ value of 5.3 nmol P per mg protein.

The maximal phosphorylation capacity of 5.6 nmol P per mg protein at an $\alpha\beta$ dimer molecular weight of 163,400 corresponds to 0.92 phosphorylation site per $\alpha\beta$ dimer. As even a highly purified enzyme preparation is not 100% pure on a protein basis (as seen by the appearance of minor protein bands beyond the two prominent bands belonging to the α and β subunits on SDS-gel electrophoresis, data not shown), this value is a slight underestimation of the true phosphorylation capacity.

Thus we conclude that every $\alpha\beta$ unit has one active phosphorylation site. As the molar binding values for ATP, ouabain and vanadate equal the phosphorylation level¹⁻⁷, our results also indicate that each $\alpha\beta$ unit can bind one molecule each of ATP, ouabain and vanadate. As the most likely subunit composition of the enzyme is $\alpha_2\beta_2$ (ref. 11), we may safely conclude that the $\alpha_2\beta_2$ tetramer has two phosphorylation sites, which can be phosphorylated simultaneously. This rules out the operation of a 'half-of-the-sites mechanism' in ($\text{Na}^+ + \text{K}^+$)ATPase from rabbit kidney.

We thank Annie M. M. Fleuren-Jakobs for technical assistance.

Approximately 20% of patients with acute lymphocytic leukaemia (ALL) have leukaemic blasts with features of pre-B cells¹ which are the recently characterized precursors of B lymphocytes in normal development (for a review, see ref. 2). Pre-B cells isolated from normal bone marrow or fetal liver, and malignant cells from patients with pre-B cell leukaemia, are rapidly dividing lymphoid cells that contain cytoplasmic immunoglobulin μ heavy chains, but have no detectable surface immunoglobulin. The resemblance of immunoglobulin-containing ALL cells to normal precursors of B lymphocytes and their availability in relatively pure preparations allowed us to explore them as models of early stages in the differentiation of the B-lymphocyte line. We report here observations on the occurrence of intermediate pre-B/B-cell phenotypes, immunoglobulin isotype switching and the asynchrony of immunoglobulin heavy and light chain expression in 30 cases of ALL and 3 cases of chronic myelogenous leukaemia in lymphoblastic crisis (CML-BC).

Heparinized bone marrow from patients with untreated ALL or with CML-BC was examined after lysis of erythrocytes with a hypotonic solution of ammonium chloride. Surface immunoglobulins were detected by immunofluorescent staining of fresh, viable cells with fluorochrome-conjugated, affinity-purified goat anti-human μ , γ , α , κ and λ antibodies, as described elsewhere³. Intracytoplasmic immunoglobulin was detected by immunofluorescent staining of cells that had been centrifuged or smeared on to glass slides, fixed in cold 95% ethanol, 5% acetic acid and washed in buffered saline as described elsewhere¹. Differently coloured fluorochromes (rhodamine and fluorescein isothiocyanates) were used to stain cells before and after fixation, which allowed us to distinguish between surface and cytoplasmic determinants in single cells. In some patients observations were reproduced using a completely different set of reagents: fluorochrome-conjugated F(ab')₂ fragments of rabbit anti-human μ , γ , α , κ and λ antibodies as described elsewhere⁴. Terminal deoxynucleotidyl transferase was detected by indirect immunofluorescence using a rabbit anti-terminal deoxynucleotidyl transferase serum⁵ and fluorescein-conjugated goat anti-rabbit Fab. Results of immunofluorescence studies represent concurrent observations of at least two of the authors.

In 1 year we found 33 patients with intracytoplasmic immunoglobulin-positive lymphoblastic leukaemia. In 31 of these at least 10% of marrow blasts contained cytoplasmic and no surface immunoglobulin, as originally observed in pre-B

Fig. 1 Surface and cytoplasmic expression of immunoglobulin isotypes in leukaemic cells. ×, Surface μ ; ●, ■, ▲, cytoplasmic μ , γ and α chains, respectively. Horizontal bars represent the mean percentage of marrow mononuclear cells expressing intracytoplasmic immunoglobulin of each class.

leukaemia. In contrast, normal pre-B cells comprise only $1.0 \pm 0.6\%$ of human marrow mononuclear cells⁶. When taken collectively, blasts of pre-B phenotype accounted for 66.7% of the leukaemic cells in these patients (Fig. 1). In individuals, however, leukaemic cells of identical morphology were sometimes found to be composed of three distinct populations based on immunoglobulin expression: cells showing no immunoglobulin, cells with intracytoplasmic immunoglobulin only, and cells with both intracytoplasmic and scant amounts of surface μ . In three patients cells of the latter type accounted for a large proportion (42, 49 and 82%) of the lymphoblasts (Fig. 1). This phenotype, also observed by Brouet *et al.*⁷ and Greaves *et al.*⁸, is thought to represent cells at a stage of differentiation intermediate between that of the pre-B and B-cell stages. Several features distinguish these 'intermediate' cells from mature B lymphocytes: they have persistent expression of cytoplasmic μ chains and the nuclear enzyme, terminal deoxynucleotidyl transferase; and in two of three cases the sparse amounts of μ chain on the cell surface were not associated with detectable light chains.

As in previous studies^{1,7}, many patients with pre-B leukaemia had a very small proportion of a leukaemic cells that expressed

cytoplasmic γ or α chains in addition to cytoplasmic μ . However, in five of our present patients, cells containing γ chains accounted for a relatively large proportion ($>10\%$) of the leukaemic population, sometimes outnumbering μ -containing leukaemic cells (Fig. 2, Table 1).

In addition to the 31 patients already described, one with ALL and one with CML-BC had a small proportion of lymphoblasts (8% and 6%, respectively) that contained only γ heavy chains. Unlike the previous cases, μ chains (and other non- γ chains) were undetectable in both the γ -positive and γ -negative lymphoblasts from these individuals. As γ -containing cells comprised $<10\%$ of mononuclear cells in the marrow of these patients and μ chains were not detected, they did not conform to our original definition of pre-B cell leukaemia. However, there is evidence for the immaturity of these leukaemic cells and for their distinction from IgG-secreting lymphoplasmablasts: (1) the distribution and intensity of immunofluorescent staining with a pattern identical to that of μ -staining in pre-B cells; (2) the co-expression of cytoplasmic γ and nuclear terminal deoxynucleotidyl transferase in double immunofluorescence studies; and (3) the absence of detectable light chains in freshly collected lymphoblasts. Note also that κ chains were found in 10% of the γ -positive lymphoblasts from the patient with CML-BC when leukaemic cells were cultured for 24 h in RPMI 1640 medium supplemented with fetal calf serum.

Cells from 15 patients were examined for surface and cytoplasmic κ and λ light chains (Table 1). In only four of these were cytoplasmic light chains found in most of leukaemic cells containing μ heavy chains. Light chains usually were present in only a small proportion of cells containing heavy chains, or were undetectable. In five patients (see Table 1, patients 1, 2, 4, 10 and 11) when leukaemic cells were examined simultaneously for light and heavy chains by double immunofluorescent staining, the expression of cytoplasmic κ chains was associated with that of γ heavy chains. No surface light chains were detected in the absence of surface heavy chains.

Analysis of leukaemic cells from our patients with ALL and CML-BC reveals that immunoglobulin expression in the pre-B group of leukaemias is less homogeneous than originally thought (Fig. 2). Cells carrying sparse surface μ , probably representing an intermediate pre-B/B-cell stage of development, were predominant in three patients. The infrequent expression of light chains relative to μ chains in pre-B leukaemic cells from most of these patients agrees with similar results reported by Brouet *et al.*⁷ and Greaves *et al.*⁹. An asynchrony in the expression of cytoplasmic μ heavy chains and light chains has also recently been observed in murine cells of pre-B phenotype from normal fetal liver¹⁰, Abelson virus-infected bone

Table 1 Cytoplasmic immunoglobulin expression by lymphoblasts from patients with ALL or CML-BC

Patient	Diagnosis	Ig heavy chain			Ig light chain	
		μ	γ	α	κ	λ
1	ALL	10	25	<1	25	<1
2	ALL	81	10	<1	15	<1
3	ALL	92	<1	<1	5	<1
4	ALL	36	13	<1	14	<1
5	ALL	99	5	<1	<1	<1
6	ALL	95	3	<1	<1	<1
7	ALL	93	4	2	3	3
8	ALL	90	<1	<1	70	<1
9	ALL	86	4	<1	87	<1
10	ALL	65	25	<1	25	<1
11	ALL	10	20	<1	20	<1
12	CML-BC	81	<1	<1	<1	<1
13	CML-BC	3	9	<1	2	<1
14	ALL	<1	8	1	2	<1
15	CML-BC	<1	6	<1	1	<1

Results are expressed as percentages of positive cells among bone marrow mononuclear cells.

Fig. 2 Phenotypes observed in immunoglobulin-containing lymphoblastic leukaemias. Six patients were selected to demonstrate the heterogeneity of immunoglobulin expression in immunoglobulin-positive lymphoblastic leukaemias. A representative cell phenotype comprises at least 5% of the leukaemic cell population. In each case a varied number of leukaemic blasts expressed no detectable immunoglobulin and could be described as 'null' phenotype. The surface μ⁺ leukaemic cells in patient *e* may represent a developmental stage intermediate between that of pre-B and B cell. Both these cells and the γ⁺ cells in patient *f* had no detectable light chains, but contained nuclear terminal deoxynucleotidyl transferase. Dashed arrows show suggested directions of differentiation.

marrow-derived cell lines¹¹, and pre-B/myeloma cell hybridomas¹². In humans the study of bone marrow and fetal liver also indicates that only a small minority (<10%) of normal pre-B cells co-express κ or λ light chains with μ heavy chains; most normal human pre-B cells express only μ (H. Kubagawa, unpublished results). In contrast to these results and observations in most patients with pre-B leukaemia, κ light chains were detected in >5% of leukaemic cells from seven of our patients, usually in μ-containing cells, and their incidence coincided with the expression of γ chains in five patients. However, the absence of γ chains in cytoplasmic μ⁺, κ⁺ cells from two patients, and the absence of light chains in γ⁺ cells from two others, precludes any simple explanations for γ and light-chain concurrence during differentiation.

The expression of a second heavy chain isotype in some of our patients' leukaemic cells has not been previously observed in normal human pre-B cells. There are two possible explanations for this: because γ chains were observed in a small population of leukaemic cells from a minority of patients with pre-B leukaemia, class switching may be a rare event at the pre-B stage of differentiation. Therefore, it would be difficult to detect a small population of γ-containing cells among the ~1% of μ-positive pre-B cells present in normal marrow using conventional tech-

niques, although we have made considerable efforts in this direction. Alternatively, the γ chains found in these leukaemic cells may reflect abnormal regulation of immunoglobulin gene expression related to malignant transformation, rather than the sequential events of normal B-lymphocyte development.

Whichever the case, our results indicate that the mechanisms responsible for the isotype switch from μ to γ chains and for light chain gene expression are operable at a stage in B-cell development before the expression of surface immunoglobulin and antigen receptors. We suggest that cells containing cytoplasmic γ chains and with the phenotypes described here, reflect early stages in the development of normal B cells, perhaps representing pathways alternative to the major sequence of maturation.

We thank Drs G. Flandrin, D. Buriot, G. Duhamel of Paris, and members of the Southwest Oncology Group, USA, for contributing samples for this study, Dr H. Kubagawa and Mrs S. Labaume for preparing antibodies and Mrs K. Nelson for technical assistance. This work was supported by US PHS grants CA 25408, CA 16673, CA 13148 and DGRST grants 80.7.0220, 78.7.3101. Natural occurrence but lack of melanotrophic activity of γ-MSH in fish

C. McLean & P. J. Lowry

Pituitary Hormone Laboratory, Department of Chemical Pathology, St Bartholomew's Hospital, London EC1A 7BE, UK

When adrenocorticotropin (ACTH) and β-lipotropin (LPH) are enzymatically cleaved in the pituitary from their common precursor molecule, a glycopeptide with an apparent molecular weight of 16,000 remains (reviewed in ref. 1). Sequencing of a cDNA copy of the bovine pituitary mRNA for the precursor molecule demonstrated that, within the region encoding the 16,000-molecular weight (MW) glycopeptide, there was a short sequence homologous with the α-melanocyte-stimulating hormone (α-MSH) contained in ACTH and the β-MSH within β-LPH². It was therefore proposed that the region of homology coded for a γ-MSH which might have biological activity, although synthetic peptides containing this sequence were shown to have poor melanotrophic activity³. In the pars intermedia further rapid enzyme modification converts ACTH to α-MSH and corticotropin-like intermediate lobe peptide (CLIP), and β-LPH to β-MSH and β-endorphin. Although smaller peptides containing the γ-MSH structure have been detected in extracts of the bovine pars intermedia^{4,5}, the major

post-translational products of the 16,000-MW fragment are present mainly as large glycosylated peptides^{1,4}. We report here that a major peptide product of the neurointermediate lobe of the dogfish pituitary which we had previously shown to lack melanotrophic activity has a γ -MSH-like structure. Therefore if γ -MSH is a peptide with a function it is not one shared with the melanotrophic hormones.

In our previous studies, peptides analogous to mammalian α - and β -MSH were characterized from extracts of the neurointermediate lobe of a more phylogenetically ancient species, the dogfish (*Squalus acanthias*)⁶, the final purification of which is shown in Fig. 1. Peak A was identified as dogfish β -MSH

Fig. 1 A_{280} ; MSH activity is shown by the hatched areas. The column (0.6 cm i.d. $\times$ 25 cm length) was developed with a concave gradient running from 20 to 500 mM trimethylamine acetate, pH 5 (total volume 150 ml), and 1-ml fractions were collected every 20 min. A, B and C denote peaks of MSH activity. (From ref. 6.)

whilst B and C were two forms of α -MSH (C was found to be the C-terminally amidated form of B). At concentrations where peaks A and B showed potent MSH activity, D and E were inactive.

Peaks D and E stored from the previous study were repurified by preparative high-pressure liquid chromatography (HPLC, 1×10 cm Spherisorb ODS $10 \mu\text{m}$) developed with a methanol gradient (40–80% in H_2O , containing 1% trifluoroacetic acid). Amino acid analysis of samples of each purified peptide after both acid and enzyme hydrolysis⁷ gave identical compositions: Asn₁, Thr₁, Gly₁, Met₁, Ile₁, Tyr₁, Phe₁, His₁, Lys₂, Trp₁ and Arg₁. E was deduced to be a C-terminally amidated form of D in view of its higher ammonia values and its more basic behaviour during purification on CM-cellulose (Fig. 1). D ($50 \mu\text{g}$) was submitted to automated sequence analysis and gave the unambiguous structure shown in Fig. 2, which also shows the equivalent sequence predicted from the bovine cDNA study and comparisons of the other two species of melanotrophins.

Although there is little sequence homology between D (and its amidated form E) and the γ -MSH bovine sequence, their lack of melanotrophic activity compared with the two other dogfish peptides, α - and β -MSH, and the poor melanotrophic activity of synthetic bovine γ -MSH peptides³ suggest that their assignment as γ -MSH peptides is correct. It is interesting to note here that the unconservative substitutions in the core sequence of dogfish β -MSH compared with bovine β -MSH (Phe for Met and Gly for Glu) have maintained its potent MSH activity whilst both γ -MSHs which have a more recognizable core sequence (Met-X-His-Phe-Arg-Trp) are comparatively inactive as melanotrophic peptides.

The poor periodic acid-Schiff staining of the dogfish (and other fishes, for example, teleosts) intermediate tissue⁸ suggests that the fish γ -MSH/ACTH/LPH precursor is not glycosylated,

Fig. 2 Comparison of the known and predicted sequences of bovine and dogfish MSH peptides. Sequence analysis of dogfish γ -MSH was carried out in the JEOL-47K sequence analyser using 3 mg Polybrene as carrier. The normal protein programme was used with 0.5 M Quadrol as the reaction buffer. The nitrogen-dried phenyl thiazolinone derivatives were converted to their phenylthiohydantoin derivatives by treatment with $100 \mu\text{l}$ 0.5 M HCl at 70°C for 10 min. After addition of $20 \mu\text{l}$ 1M trisodium citrate the derivatives were directly analysed by HPLC (Altex-ODS, 10–40% acetonitrile/tetrahydrofuran in 10 mM triethylamine phosphate, pH 3, 20 min). Confirmation of samples was carried out by amino analysis after back hydrolysis with HI (150°C , 24 h).

as in the mammals, near the γ -MSH region. It may be this lack of glycosylation that allows the precursor to be processed to the two γ -MSH-like peptides in fish but not in mammals. Their occurrence as major peptide products of the pars intermedia and the C-terminal amidation suggest a biological role for these peptides in the fish but it is unfortunate that the term γ -MSH was coined for such peptides when they have little if any, melanotrophic activity in an animal, like the dogfish, which responds to changes in background by altering skin pigmentation.

Slow-reacting substances (leukotrienes) contract human airway and pulmonary vascular smooth muscle *in vitro*

C. J. Hanna*, M. K. Bach†, P. D. Pare* & R. R. Schellenberg*

*University of British Columbia, Pulmonary Research Laboratory, 1081 Burrard Street, Vancouver, British Columbia, Canada V6Z 1Y6

†Department of Hypersensitivity Disease Research, The Upjohn Company, Kalamazoo, Michigan 49001, USA

During a type I allergic reaction histamine, slow-reacting substance of anaphylaxis (SRS-A) and other mediator substances are elaborated from specific tissue sites¹. In allergic asthma these sites are in the lung and the mediator substances cause airway obstruction by contracting smooth muscle and altering mucociliary function²⁻⁴. Unlike histamine, slow-reacting substances (SRSs) have been assessed very little for their roles in obstructive airways disease. This has been partly due to the fact that their chemical nature was unknown until recently and thus pure samples were not available for pharmacological studies. However, SRSs isolated from both immunological and non-immunological reactions have been identified as a combination of two related lipid substances—leukotriene C₄ (LTC) and leukotriene D₄ (LTD)^{5,6}; thus it is now possible to use pure SRSs (leukotrienes) in pharmacological studies of airway smooth muscle. LTC and LTD have been shown to contract guinea pig tracheal and lung parenchymal strips⁵ but there is no evidence that these substances produce similar effects on human lung tissue. To clarify this, *in vitro* pharmacological studies were done to determine the actions of LTC and LTD on smooth muscle strips of human bronchus, pulmonary vein and artery, and lung parenchymal tissue containing smooth muscle components and pleura. As indicated in a preliminary report⁷, all four types of tissues contracted in a dose-dependent fashion to the leukotrienes, although these substances only function as partial agonists.

Lung tissues were obtained from 14 patients undergoing lobectomy or pneumonectomy for isolated peripheral pulmonary lesions. Samples of bronchus, pulmonary vein, pulmonary artery and parenchyma were dissected free and placed in oxygenated Krebs' solution. The bronchial, pulmonary venous and pulmonary arterial samples were then cut into spiral strips 1×4×40 mm; parenchymal strips, with and without pleura, were cut in strips about 5×5×40 mm. These were placed in an organ bath system containing Krebs' solution and drug responses were examined. SRS peaks I and II were obtained from rat peritoneal monocytes by methods described elsewhere^{6,8}. Peak I was identified as leukotriene D₄ (ref. 9) and peak II as leukotriene C₄ (formerly designated LTC-1)¹⁰.

A cumulative drug application procedure¹¹ was used to study the contractile effects of all the agonists, as well as the antagonistic action of FPL 55712 against the leukotrienes, on the four types of lung tissue. All drug concentrations are expressed in molar units. LTD and LTC molarities were determined by converting Upjohn SRS units of activity into moles of leukotriene (LTD: 1 U = 20 pg, molecular weight (MW) = 495; LTC: 1 U × 24 ± 2 pg, MW = 625) and dividing by the dilution volume in litres.

The log dose-response curves for carbachol, histamine (both Sigma), LTC and LTD on human bronchial smooth muscle are shown in Fig. 1. Carbachol and histamine elicited fast onset, sustained, dose-dependent contractions, although the bronchial tissue was consistently more sensitive to carbachol over the full range of the dose-response curve. Carbachol also produced the greatest magnitude of contraction compared to the other agonists. Both carbachol and histamine were active over a wide dose range (5×10^{-9} – 5.5×10^{-4} M) with pD₂ values (calculated as $-\log \text{ED}_{50}$) of 6.301 and 5.658, respectively. Submaximal effects of both agonists were easily reversed when they were washed from the organ baths.

However, responses to the leukotrienes were markedly different: both LTC and LTD caused human bronchial smooth muscle to contract but the responses had a delayed onset and slow development time. The contractions were well sustained (that is, they did not fade) and were dose-dependent. As can be seen in Fig. 1, the bronchial tissue was most sensitive to LTC although this leukotriene produced maximum responses that were only 60–70% that of the maximum responses to carbachol.

Fig. 1 Log dose-response curves for carbachol (●), histamine (◆), LTC (▲) and LTD (■) on human bronchial smooth muscle. Tissues obtained from patients undergoing thoracic surgery for carcinoma were cut into spiral strips and maintained in 20 ml jacketed organ baths containing oxygenated Krebs' solution, pH 7.4, at 37 °C. Contractions were measured semi-isometrically with Grass FT .03 C force displacement transducers and recorded on a Beckman R511A polygraph. Initial tensions ranged from 1 to 2 g; raw data were collected as active tension (g). Data points are expressed as a percentage of the maximum carbachol response (left ordinate) and a mean active tension scale (right ordinate) is shown for comparison. Each point represents the mean ± s.e.m. of three to seven experiments.

Fig. 2 Original polygraph tracings of the responses of human bronchus (BR), parenchyma (PAR), pulmonary vein (PV) and pulmonary artery (PA) to selected agonists and the antagonist, FPL 55712. Contractile responses are shown in terms of active tension (g) generated per unit of time (min). Drugs were added to the bath in a cumulative manner. LTD, leukotriene D₄; LTC, leukotriene C₄.

LTD similarly acted as a partial agonist. Both the leukotrienes were active over a narrow dose range (3×10^{-9} – 5×10^{-8} M) with pD_2 values of 8.022 for LTC and 7.620 for LTD. Human bronchial tissue was more variable in its responsiveness to LTC and LTD than to carbachol or histamine. It was also found that leukotriene-induced contractions were reversed when these substances were washed from the baths. Furthermore, exposure of tissues to leukotrienes (followed by washing) before addition of another agonist did not alter the tissue responses to the second agonist.

The SRS-A antagonist, FPL 55712 (Fisons), inhibited LTC- and LTD-induced contractions of human bronchial smooth muscle. The upper trace in Fig. 2 shows the response of a human bronchial strip to LTD ($600 \text{ U} = 2.4 \times 10^{-8} \text{ M}$) followed by the addition of FPL 55712. The rate of inhibition was slow and the concentrations of FPL 55712 required to abolish completely the LTD contraction were high ($2.6 \times 10^{-4} \text{ M}$), although the antagonism was clearly dose-dependent. No specific anti-histamine effect was observed with high doses of FPL 55712; the antagonist alone had no effect on the tissues.

The contractile effects of the leukotrienes and other selected agonists on human parenchymal tissue, pulmonary vein and pulmonary artery were also examined to a limited extent. Examples of traces are shown in Fig. 2. In general, the vasoactive amines, histamine or 5-hydroxytryptamine, were more active than LTC or LTD on each of these three types of lung tissue. The parenchymal tissue was slightly more sensitive to LTC (threshold 150 U) than LTD (300 U) and gave a slightly greater maximal contraction (LTC 60%, LTD 35% of the histamine maximum). Pulmonary vein and artery were not as responsive to the leukotrienes as the airway tissues and the responses were characteristically slow in onset and development compared with the amines.

These results suggest that LTC and LTD may act as airway spasmogens when released by an allergic reaction in the human lung. Our data show that human bronchial smooth muscle was very sensitive to the leukotrienes although both substances acted as partial agonists compared with carbachol. Previous studies^{12–14} have shown that human bronchial smooth muscle contracted in response to crude preparations of SRSs; however, our results show that the distinctive 'slow reaction' is caused by the leukotrienes. Dahlen *et al.*¹⁵ have described similar findings with LTC and LTD.

The inability of the leukotrienes to elicit a maximum contractile response, the delayed onset of contraction and the slow rate of FPL 55712 antagonism suggest a mechanism of action on human lung smooth muscle which differs from that seen for other agonists. Such differences indicate that the mechanism of action of the leukotrienes is not closely linked to the contractile apparatus.

In these studies, neither LTC nor LTD had preferential activity on central (bronchial) versus peripheral (parenchymal) airway smooth muscle. As the parenchymal tissues obtained were from patients with usually significant emphysema, the reactivity varied considerably from one tissue to another and we may thus have limited our ability to see a preferential peripheral response. However, this seems unlikely because unreactive tissues failed to respond to all agonists, whereas reactive parenchymal strips not only contracted to agonists but in the same approximate dose range as for the bronchial strips.

These results suggest the possibility that leukotrienes C and D may play a major part in human bronchial asthma.

Histamine and carbachol were from Sigma and FPL 55712 was from Fisons. We acknowledge the support of the Canadian and British Columbia Lung Associations and B.C. Health Care Research Foundation. We thank Drs J. C. Hogg and J. M. Nelems for their contributions and Mrs L. Hare for typing the manuscript. C.J.H. is a Canadian Lung Association Fellow.

BOOK REVIEWS

Genes and culture: an awkward hybrid

Richard Dawkins

THIS little book is an attempt by authors who are sophisticated and accomplished in their own field of evolutionary biology to fit human culture into their scheme of things. I therefore opened it with some anticipation. The first chapter is a sensible and persuasive exposition of the claim, which will be uncontested by all who understand what a modest claim it truly is, that living organisms may usefully be treated as machines programmed to propagate copies of the genes responsible for the programming. The authors note the danger that such language

can lead the unwary imagination to a forest glade where tiny pixies work their will by casting spells on inanimate objects, but such good literary fun should not bother the reader who keeps firmly in mind the true aimless nature of DNA and who remembers that the apparently gene-serving behaviour of organisms is an equally aimless consequence of natural selection. Counting on our readers to distinguish the laws of natural selection from the spells of pixies, we will use the image of a purposeful gene to pursue the problem of the origin of learning [p.2].

Ah what touching trust; I cannot resist a wistful sigh. Pixies, hobgoblins, demons and ogres, there will be readers who will find them all lurking in the most unassuming and innocent prose, provided only that "gene" is juxtaposed with language redolent of the boggy world of computers and automation.

Pulliam and Dunford make use of the language of automation in their second chapter, "The Cybernetic Lizard vs. the Toxic Ants". This chapter is part of their long drawn out construction of a niche for learning in the genes-eye view of life. The ethological reader familiar with Konrad Lorenz's classic *Evolution and Modification of Behavior* (Methuen, 1966), or with his later work *Behind the Mirror* (Methuen, 1977), may wonder if the conclusion Pulliam and Dunford reach, important and correct as it is, really needs quite such sustained and protracted rediscovering. Once you start thinking functionally, it certainly makes sense that "the genes, by controlling neural development of the brain, set a learning program that determines how flexible or stereotyped an individual's behavior will be" (p.22). And, moving to the next chapter, "Emotion and Decision", ethologists will need little persuading that evolution of emotions has a lot to do with "genetic selection for decision criteria to

Programmed to Learn: An Essay on the Evolution of Culture. By H. Ronald Pulliam and Christopher Dunford. Pp.138. (Columbia University Press: 1980.) \$10, £5.77.

guide learning. Genes exert control over the behaviour of their survival machines by controlling the development of the neural mechanisms that determine which experiences evoke which emotions" (pp. 26-27). Konrad Lorenz and other ethologists should be given some credit for long ago hammering home the idea that "the genes had to define good and bad for their agent", and that "The solution has been to create emotional sensations within the animal agent which makes it want to avoid 'bad' experiences and repeat 'good' ones" (p. 41).

The authors are now ready to move on to their main subject of culture, which they interpret in the common biological sense of traditional behaviour inherited by non-genetic means. Their chapter "Shortcuts to Learning" makes the reasonable point that, among the "values" which a successful gene might be expected to build into its agents' learning programs, is a predilection for copying the ways of respected individuals. "We might sometimes think to ourselves, 'If they say it is good, it is probably good'." An animal can shortcut the normal learning process by picking up useful tricks from other animals. The Japanese macaque stories give their usual good service in this connection and, mercifully, we are spared the now almost obligatory emphasis on the fact that the great Imo was both female and young when she made her brilliant innovations.

After an interlude on economic exchange theory, we move on to "The Mathematics of Culture", a useful summary of the Cavalli-Sforza and Feldman models of cultural inheritance. There are, of course, immense difficulties in the path of any attempt to apply population genetics-like mathematics to cultural inheritance, but the very difficulties themselves are likely to be illuminating and should not be taken as an excuse for funkling the attempt. The possibility that cultural inheritance might, in some sense, be treated as particulate rather than blending is one that intrigues me. This is my way of wondering if "cultural logic conforms to genetic logic" (Chapter 7). In passing I could not help

noting that Pulliam and Dunford faithfully replicate the notorious cultural mutation in the citation of W. D. Hamilton's "The Genetical Evolution of Social Behaviour" (J. Seger and P. Harvey *New Scientist*, 87, 50-51; 1980). This would have been an especially illuminating example for Pulliam and Dunford themselves to have used since it seems not to be a pure, undirected mutation at all. As Seger and Harvey point out, the "mutant" reading, "The Genetical Theory of Social Behaviour", has arisen three times independently, and is almost certainly a cultural legacy from that most admired of tribal ancestors, R. A. Fisher, and his "The Genetical Theory of Natural Selection".

The authors may or may not establish their anthropological credentials by going to town on "kinship". An impressive few pages bristle with words such as matrilineal and patrilineal. They coin the interesting phrase, "cultural coefficient of relationship", but actually it turns out to be less interesting than I expected it to be. Instead of being the cultural equivalent of the genetic coefficient of relationship, they apply the term to an awkward hybrid between cultural and genetic notions. They seem unable quite to emancipate themselves from the assumption that genetic "fitness" (capacity to propagate copies of one's genes) has some kind of privileged priority over its cultural equivalent (capacity to propagate one's ideas, etc.). Thus, instead of stressing that, in the domain of cultural inheritance, "brothers" may be defined as those (genetically perhaps unrelated) who have sat at the feet of the same master, they come up with what is really only a kind of culturally weighted version of the genetic coefficient.

If a child's parents have different ideas on a particular issue, let us say that a child learns the father's idea with probability P and learns the mother's idea with probability M. Then, the probability that two siblings learn the same idea from the same parent is $P^2 + M^2$. . . This is the probability of cultural identity by descent and can be called the *cultural coefficient of relationship*. Like the genetic coefficient of relationship, the cultural coefficient can be calculated for any pair of relatives.

But if such a cultural coefficient can be calculated for any pair of genetic relatives, can't it also be calculated for any pair of individuals whether genetically related or not?

The last chapter, "The Legend of

Eslok", is rather queer. If I understand it aright, the intention is sensible enough: to use a parable about an imaginary tribe, the Koltinnopinnu to make a point about the conservative role of traditional ritual in preserving ancient wisdom vital for group survival. But the imaginary legend is dragged out with almost Tolkienian attention to gratuitous detail, including learned footnotes on fine points of the fictitious language of the imaginary Koltinnopinno (plurals are formed by

adding "o"). I was left with the feeling that I must be missing the point of the story, since I couldn't see the symbolic (or anagrammatic?) significance of these details. Well, if it comes to that, maybe I missed the point of the whole book: there has to be *some* explanation for my disappointment with it. □

Surprising structures of nucleic acids

C.W. Hilbers

Nucleic Acid Geometry and Dynamics. Edited by R.H. Sarma. Pp.424. (Pergamon: 1980.) Hbk £25, \$55; pbk £11, \$24.50.

IN molecular biology nucleic acids are probably the most discussed of all biological macromolecules. Yet, until the early 1970s, information about the structure these molecules can adopt was mainly based upon results from X-ray diffraction experiments on DNA or RNA fibres. During the past decade the situation has rapidly changed. Several events have contributed to this development. Investigators have been able to crystallize the relatively short transfer RNA and determine its structure to atomic resolution. In addition, newly developed organic synthetic methods have permitted the preparation of well-defined fragments of RNA and DNA, so that single-crystal analysis of these oligonucleotides can be performed, and techniques (NMR, T-jump) for the high-resolution study of the structure and dynamics of nucleic acids in solution have become available.

All of these developments have led to surprising results, outstanding among which is the finding that nucleic acids possess a conformational flexibility that can give rise to structures far more complex than the simple double helix.

Some of the excitement pervading the field is reflected in this book. It is a collection of 16 review chapters by different authors in which the structure and dynamics of nucleic acids are discussed in great detail. The first chapter introduces the nomenclature of nucleic acids, and is followed by a discussion of the way in which structural information can be deduced from NMR measurements and a description of the basics of single-crystal X-ray diffraction techniques as applied to nucleic acids. It is somewhat confusing that although different systems of nomenclature are in current use for nucleic acids and are employed throughout the book, only one is presented in the first chapter. Also, one would have preferred the scaling of the NMR spectra to be given in ppm instead of in Hz.

In the following chapters the basic theme of the book unfolds. Sarma describes the spatial configurations of different forms of DNA, and Seeman gives an account of the crystal structures obtained for oligonucleotides. Lerman's proposal in 1961 that aminoacridine dyes bind to DNA by intercalation between stacked bases has now been verified at atomic resolution for a number of planar dyes intercalated in dinucleotides. Accounts of progress in this area are presented by Sobell and by Berman and Neidle. Rich and his co-workers relate the conformational changes in the sugar phosphate backbone of RNA and DNA fragments, introduced by the intercalation of planar dyes, to the changes occurring in the backbone of tRNA resulting from the intercalation of a base between two consecutive bases.

The intercalation of dyes is taken further by Patel, by Krugh *et al.* and by Crothers *et al.* who discuss the information obtained on this subject from solution studies. Fluctuations in nucleic acid structure as monitored by NMR, ESR and tritium and deuterium exchange techniques are covered by Kallenbach and co-workers and by Lerman and co-workers. Finally, theoretical aspects of the structure, flexibility and accessible surface areas are dealt with in the three chapters by Broyde and Hingerty, Olson, and Alden and Kim.

The book is recommended to anyone involved in structural studies of nucleic acids. It contains a wealth of information, written by experts and illustrated with beautifully coloured molecular models many of which were drawn by Irving Geiss. It is not complete, however, in that it does not contain a chapter devoted to the structure and dynamics of tRNA. A potential buyer should also be aware that a large part of the material has already appeared in *Stereodynamics of Molecular Systems*, edited by R.H. Sarma and published by Pergamon. □

Stuck on bacteria

N. Sharon

Bacterial Adherence. Receptors and Recognition, Series B, Vol.6. Edited by E.H. Beachey. Pp.466. (Chapman and Hall/Methuen Inc.: 1980.) £27.50, \$69.95.

IT is a truism that in order to inhabit or infect a susceptible host, bacteria must be able to "stick" to the tissue surfaces of the host. Surprisingly enough, until the early 1970s little attention was paid to the problem of bacterial adherence to cell surfaces, its molecular mechanism and possible role in host-parasite interactions. The recent explosion of activity in this area may be ascribed, at least in part, to the current intense interest in receptors on cell surfaces, and in their role in intercellular recognition. No wonder that the first treatise on bacterial adherence appears as part of the series on "Receptors and Recognition".

The 14 chapters in the book are all written by experts active in the field, including several of the pioneers who for some years worked almost alone on bacterial adherence. Notable among them are J.P. Duguid from the University of Dundee and R.J. Gibbons from Boston. The first contribution, by I. Ofek and E.H. Beachey, is an excellent overview of the field. In the subsequent 11 chapters, emphasis is either on adhesion to different surfaces (mucosal, dental or of plants, for example), on the adhesive properties of specific organisms (Enterobacteriaceae, *Vibrio*, *Neisseria*, for example), or the binding properties of bacterial appendages (fimbriae or pili) and surface polymers (lipoteichoic acid). This loose organization is probably a reflection of the dearth of knowledge of the basic mechanisms involved in adherence. One of the two concluding chapters deals with recognition systems between eukaryotic cells, a topic of relevance to the prokaryote-eukaryote system of bacterial adherence, and the other with prospects for prevention of the association of harmful bacteria with most mucosal surfaces.

From reading the book it is evident that the adherence of many bacteria to epithelial cells is mediated by complementary molecules — adhesins on the bacteria which react with receptors on the cells in a lock and key manner. In the case of *Escherichia coli* and other Enterobacteriaceae, the adhesins are lectin-like molecules in the form of fimbriae that can bind reversibly to sugar residues (predominantly D-mannose) on the surface of the epithelial cells, whereas certain mycoplasmas appear to bind in a similar manner to sialic acid residues. Streptococci, on the other hand, appear to bind to cells via their surface lipoteichoic acid. Much remains, however, to be learned about the nature of the adhesins on other bacteria and about the receptors on the tissues, none of which

has been characterized and about which little is known. More importantly, there is a need for conclusive evidence on the role of adherence in natural infection; if the adhesins play a central role in the ability of pathogenic bacteria to launch infection, then the prevention of adhesion should be an effective way to protect against bacterial infections. This could hopefully be achieved by the application of specific receptor analogues or antibodies to the adhesins.

On the whole, the various chapters are well written with not too much overlap. The references are up to date and the tables abundant and clear. There are many illustrations and, with a few exceptions, they are of high quality, including several artistic scanning electron micrographs

which are most impressive. However, the book suffers from the modern malaise of poor indexing — the number of entries is insufficient and even major items such as adhesins, agglutination, mannose, mucus, virulence and yeast cells have not been included.

This is a valuable book, which should be read not only by researchers in the growing field of bacterial adherence, but also by all those interested in infectious diseases and microbial ecology in general, and all students of cell surface receptors and recognition. □

Perspective on the flowering of Fermiology

Walter A. Harrison

Electrons at the Fermi Surface. Edited by M. Springford. Pp.541. (Cambridge University Press: 1980.) £35, \$85.

THIS *Festschrift* is a fitting tribute to Professor David Shoenberg, whose experimental studies of electrons at the Fermi surface span nearly a half century. In 1937, he pioneered the use of the de Haas-van Alphen effect, which arises from the quantized orbits of electrons moving in a magnetic field, to determine the electronic structure of the semimetal bismuth. When such studies were extended to metals, however, they correlated only poorly with knowledge of other properties of the metal and the contemporary theory of electronic structure. The experimental effect tended to "see" the tiniest pieces of Fermi surface, the abstract surface in momentum space (or wavenumber space) which is the

boundary separating electronic states which are occupied in a solid from those which are empty. Most properties, and available theory, focused upon grosser features, so there was little confrontation of theory and experiment. In the early 1950s it was gradually recognized that the de Haas-van Alphen effect was giving unambiguous geometrical information about the Fermi surface, in contrast to properties such as conductivity which depend upon a muddle of geometry, dynamical properties and scattering. The relevant question became clear: what is the *true* Fermi surface? This, rather than: which model of the electronic structure gives the best fit to experiment?

Lifshitz and Kaganov give historical perspective to this period in the first contribution to the *Festschrift*. Their view was of an arbitrary dispersion law for electrons

which was to be deduced from experiment. Indeed, in 1954 Lifshitz and Pogorelov set up a mathematical scheme to deduce the Fermi surface unambiguously from de Haas-van Alphen data, assuming only that the surface was convex and had a centre of symmetry. In 1956, Gunnarsen, a student of Shoenberg, carried this out in detail for aluminium. He needed to sketch in data for directions of field where the effect disappeared but he could then deduce the presence of cushion-shaped segments of Fermi surface. In hindsight this was misleading, since the real Fermi surface consisted of a set of cylindrical tubes; the missing data were different from what he assumed. A study of lead by Gold, another student of Shoenberg, quickly followed and appeared in 1958. Gold came up with similar data, which he interpreted as somewhat larger cushion-shaped segments — these also turned out ultimately to be a set of tubes. However, Gold had other data and he made a nearly-free-electron construction which led to a very intricate, but qualitatively correct Fermi surface. Though he did not have all of the surfaces matched to the correct data, his study pointed the way to the future: predict a Fermi surface from approximate theory and tune the result by experiment. Lifshitz and Kaganov indicate how difficult it was to accept the nearly-free-electron theory until forced to by its many quantitative successes. One can understand why they were not persuaded by the theoretical arguments in its favour by reading the following contribution on many-body effects by Wilkins; a series of customary assumptions can be stated, but success is their principal justification.

The nature of the study of electrons in metals changed at just the time of Gold's work. Pippard had deduced a Fermi surface for copper, published in 1957, using the anomalous skin effect. He also needed a starting picture, which in his case was the volume of intersection of three mutually perpendicular cylinders. In 1958, Shoenberg succeeded in observing de Haas-van Alphen oscillations in a whisker of copper. By 1960, at the famous Fermi Surface Conference in Cooperstown, New York, the multiply connected Fermi surface of copper had been confirmed and the essential correctness of the nearly-free-electron nature of simple metals established. In addition, other techniques, such as the magneto-acoustic effect, had been developed and applied to Fermiology, though the de Haas-van Alphen effect, because of the high order of the oscillations, remained the champion for precision. This flowering of techniques is reflected in the Lifshitz-Kaganov chapter and, most appropriately, in the simple but complete description of the Shoenberg effect in Pippard's contribution.

The subsequent history of the field is also well documented in this book. Once experiment had confirmed and refined the approximations used in band theory, and

David Shoenberg (left) and Brian Pippard discuss a model of the aluminium Fermi surface at the Cooperstown conference, August 1960.

Courtesy of B. W. Roberts, General Electric Research and Development Center

computer technology advanced sufficiently, theory could reliably predict the Fermi surfaces even of transition metals, and ultimately most other properties of these complex systems. The status of this theory is clearly described by Mackintosh and Andersen; indeed, we have the "great calculating machine" postulated by Wigner and Seitz in 1955 which has turned out to be much more interesting than they anticipated. Theory and experiment have moved on to ferromagnetic materials (described in the contribution from Lonzarich), to strained materials (Fawcett, Griessen, Joss, Lee and Perz) and dilute alloys (Coleridge). The de Haas-van Alphen effect has been pushed to extraordinary precision (Coleridge and Templeton) and the waveshapes, as well as the periods, exploited (Higgins and Lowndes). Information about electron scattering times has been extracted (Springford) and can be utilized in transport properties (Chambers).

These are authoritative and well-written articles, with a cohesion arising from the focus on Shoenberg's interests. There is, inevitably, some inconsistency of level and emphasis in such a combined effort and, in this case, an interesting set of repetitions:

the multiple presentations of Fermi liquid theory and of the density functional method reflect the central position which these concepts play in our understanding of metals.

Where will this field go from here? One might have thought that the simple-metal studies had served their purpose by 1960 in leading to pseudopotential perturbation theory which enabled the development of elementary theory of virtually the entire range of metallic properties, and yet that was only the beginning of what Higgins and Lowndes call the "decade of Fermiology". Fermi-surface parameters have now found their way into some physics handbooks so that they become an end in themselves. One could argue that transition metals have been brought into the state of grace of the simple metals and that Fermiology has again served its purpose. However, this field, which is so closely identified with David Shoenberg, seems to carry enough momentum to continue on with no sign of flagging. □

Walter Harrison is Professor of Applied Physics at Stanford University and was involved in the development of the theory of metallic Fermi surfaces.

Confusing collisions

I. S. Grant

Deep-Inelastic and Fusion Reactions with Heavy Ions. Lecture Notes in Physics, 117. Edited by W. von Oertzen. Pp.394. (Springer-Verlag: 1980.) DM49, \$29.

THIS volume contains the proceedings of a symposium held in October 1979 at the Hahn-Meitner-Institut in Berlin. The symposium was chosen as the occasion to dedicate the heavy-ion accelerator VICKSI, which had then been running for almost a year, and to celebrate the centenary of the births of Otto Hahn and Lise Meitner. Hahn and Meitner were associated with the discovery of fission, and it was fitting to devote the symposium to recent studies of the macroscopic behaviour of nuclear matter using heavy ion fusion and deep inelastic reactions.

The experimental papers present evidence for a bewildering variety of different processes which may occur in the collision of two heavy ions. The binary reactions described as fusion fission, fast fission, deep inelastic and quasi-elastic scattering are not clear-cut, but merge into one another in different regions in the space of mass and energy transfer. Nevertheless, it is clear that different phenomena are involved which potentially contain a great deal of information about the dynamical behaviour of nuclear matter. This potential is not easily realized, partly because of the experimental difficulty in recording all the information which may be relevant in each collision, and also because of the obscuring effect of various mechanisms which may contribute to the de-excitation of the composite system or the primary products of the binary reaction. As well as evaporation and fission, there are pre-equilibrium processes which lead to the emission of light particles and which are described in terms (hot spots, jets) which are notions rather than observed entities.

Naturally, the theoretical picture is also confused. One section of the proceedings consists of four theoretical papers all taking a different view of heavy ion collisions. The topic is at the interesting stage when the relationships between its different aspects are not well understood. In a fast-growing field, the proceedings of a symposium held at the end of 1979 are bound to seem a bit dated, but this volume is still a useful survey. □

I. S. Grant is a Senior Lecturer in the Nuclear Structure Group at Manchester University.

Corrigendum

● In the review of *The Principles of Human Biochemical Genetics*, 3rd Edn, by Harry Harris (*Nature* 290, 72) the prices should read: hardback \$65.75, Dfl.135; paperback \$26.75, Dfl.55.

Polemics for palynologists

Peter D. Moore

The Northwest European Pollen Flora, Vol. II. Edited by W. Punt and G.C.S. Clarke. Pp.265. (Elsevier Scientific: 1980.) \$63.50, Dfl.130.

THE second volume in this series will be welcomed by botanists working in such areas as taxonomy, Quaternary palaeoecology, and aerobiology. It follows the first volume in the series in that it consists of a collection of palynological accounts of families which have previously been published in the journal *Reviews of Palaeobotany and Palynology* (Vols 23-28). This practice of reprinting the papers is somewhat inefficient and in future the series will be continued in the form of special issues of the journal dealing specifically with the pollen flora. It is to be hoped that these future volumes will be widely publicized for the sake of those who do not subscribe to the journal and that the special issues will be available separately.

The papers in this volume maintain the high standards set in the first, both in terms of the critical and helpful keys and descriptions, and also the excellent photographs (light and scanning EM). From the palaeoecologist's point of view, particular welcome will be given to the accounts of the Saxifragaceae and Plantaginaceae. In the former, Verbeek-Reuvers takes a fairly conservative position when compared with that of Ferguson and

Webb (*Bot. J. Linn. Soc., Lond.* 63 295; 1970). He emphasizes the problems in distinguishing certain species on the basis of pollen, *Saxifraga aizoides* and *S. oppositifolia* for example. His caution should encourage many palaeopalynologists to go back to the type material and, where necessary, to increase the number of collections of each type to assess the range of variation here described.

In the Plantaginaceae, the differentiation of *Plantago major* and *P. media* is maintained, but the scanning electron micrographs serve only to make one wonder about the criteria upon which it is based. In *P. media*, microechinae (or scabrae) are visible under phase contrast light microscopy, covering the entire exine surface, whereas in *P. major* these are unclear and often totally invisible on the surfaces of verrucae. The SEM pictures of Clarke show that both pollen types possess these scabrae, so it is difficult to understand why they are so obscure on *P. major* under the light microscope.

Other families described in the volume include Solanaceae, Boraginaceae, Valerianaceae, Aceraceae, Haloragaceae and Papaveraceae. It is a book to which all serious palynologists should have ready access. □

Peter D. Moore is Senior Lecturer in the Department of Plant Sciences, King's College, University of London.

2 April 1981

Personal privacy is absolute privacy

How strictly should the rules of privacy apply to the huge banks of personal data now accumulating in the computers of public and private organizations? The European Science Foundation has raised in the past few weeks an intriguing twist on the conventional view that privacy means nothing unless it is absolute. While acknowledging that private persons are entitled to protection, the foundation says that researchers should have access to banks of otherwise confidential data in the interests of "freedom of research". Thus, in its "statement concerning the protection of privacy and the use of personal data for research", the foundation says that governments planning to model legislation along the lines suggested by the Council of Europe's convention on the protection of privacy should be sure to permit access by researchers to otherwise secret data banks. The issue thus raised is intricate, and potentially explosive. The statement in which it is embodied is a much diluted version of an earlier proposal which the General Assembly of the foundation in 1979 would not endorse. Its origins lie in the deep conviction of many social scientists that, as things are, valuable information of potentially great value in the understanding of society is denied to them. But it is unlikely that governments will respond as they would wish to the foundation's proposals. Moreover, there are good reasons why they should not do so.

Of the potential benefits of access by researchers to confidential data, there is very little doubt. In most industrialized countries, publicly compiled data banks would be gold mines for social scientists. Access to computerized health records would make possible far more accurate assessments of the pattern of disease, morbidity and sheer malingering than are possible at present. Access to census data would permit more sensitive studies of marriage patterns, the incidence of social deprivation and of poverty, than the official census takers usually embark on. Access to income tax records would make possible more accurate estimates than those now available of the incidence of wealth within communities — and perhaps even the incidence of tax evasion. In many respects, these data would be of superior quality to that which can be gathered by social scientists themselves using the more traditional methods of survey research. And there is at least some reason to suppose that the benefits would be substantial. More would be learned about the behaviour of different groups within communities than is possible with existing techniques. The frustration of the social scientists that these data are not available to them is understandable. But it is a frustration with which they will have to live for many years to come.

In the past several years, governments have only slowly woken up to the need for protecting personal data held in computer files. Nobody should underestimate the difficulties, the chief of which is the ease with which large quantities of data of a personal character can be stored and then made accessible. In the old days, ordinary people could rely on the difficulty of extracting meaningful data from shelves full of paper files as an assurance of confidentiality. But even where governments have recognized that their citizens are entitled to know that their private affairs will not be broadcast to all who seek to know, problems have arisen in deciding what limits should be placed on the transfer of information from one public authority (say the income tax department) to another (say the police). In equity, there are the strongest reasons why even government departments should be constrained within more or less watertight compartments. It will be a long time before most citizens in advanced societies can be

assured of that. Indeed, outside the United States, enlightened by the Freedom of Information Act, few governments admit the principle that citizens have a right to check data about themselves that may be recorded in the public files. The Council of Europe's convention on privacy is still very much an ideal. It will be an uphill struggle to ensure that it is widely adopted.

This is only one of the reasons why the European Science Foundation's proposal is, at this stage, unhelpful. Rightly or wrongly, it can only raise in ordinary people's minds the fear that supposed guarantees of privacy are not to be taken seriously. And although the foundation's statement suggests that scientists given access to confidential files should be required to follow rules of good conduct, and that they should not make identifiable personal data public without the consent of all those concerned, assurances to this effect will be unpersuasive and legally unenforceable. For where legislation of privacy is contemplated, the onus of responsibility for keeping confidentiality rests with identifiable individuals, the custodians of the sensitive data banks. It is unthinkable that this responsibility could be effectively derogated to whichever academic researchers chose to interest themselves in particular data banks — and unlikely that the researchers would be willing to accept it. The European Science Foundation's proposal is therefore ill-timed.

Scenarios on energy

Last week was a milestone in the short history of the International Institute for Applied Systems Analysis in Vienna, the research institute to which seventeen national academies now provide financial support. For the institute at last published a summary report of its gigantic energy study, on which more than 140 people have been engaged, off and on, since 1973. Readers of the document, *Energy in a Finite World* (Ballinger Publishing Company, \$16.50; Harper and Row Ltd, £12.50) will be of two kinds — those who want to know whether they (or their grandchildren) will be shivering from cold in the year 2030 (when the period covered by the bulk of this study ends) and those who wish to know — perhaps because they have to help find the funds to keep it going — whether the institute's reputation will be enhanced by the appearance of its first important document. On both counts, perhaps in the nature of the questions, the answers are disappointing, even frustrating. As energy scenarios go, the institute's study is more cheerful than most others, but its optimism is so hedged about with qualifications that many fond grandparents will nevertheless think of converting their legacies into string vests and other ways of keeping warm. And the study itself, however impressive its credentials — the leader of the team was Professor Wolf Häfele, a heavyweight in all senses of the word — is deficient in that it fails to acknowledge that the problem of energy is no longer technical but political.

It is now conventional to say that there has been an energy problem since the second half of 1973, when the members of the Organization of Petroleum Exporting Countries (OPEC) abolished by the stroke of a pen what had been until then the most valuable of the developed world's energy resources — crude oil at a price of \$1.50 a barrel. (The same oil costing \$32.50 a barrel seems a very different commodity to those who use it.) The institute's study, urging that those preoccupied with the energy

crisis should take a long view, avoids the trap of suggesting that the energy problem came of age in 1973. The truth is, of course, that it has been with us always. Was not the case for nuclear power in the 1950s based on the assumption that oil reserves would be exhausted in a couple of decades or so? Did not the great W.S. Jevons, leader of the Manchester Liberal School in the 1860s, bemoan the condition of Britain when the coal ran out? For the past 4,000 years, since the first machines were invented, communities of different kinds have found themselves in difficulties for lack of the means for driving their machines. If there is anything special about 1973, it is that so many complacent governments of oil-importing states were prepared to believe that oil-producing states would go on indefinitely selling their oil in whatever quantities were demanded and at a knockdown price. This perspective is a plus for the institute.

So what is special about the present period? The institute's report deals with the period 1975–2030 and starts with a daring but realistic assumption — population growth in the world as a whole during that period will be faster than in any previous time, but will afterwards begin to level off. The assumption is daring because most comparable studies have assumed that population growth will continue and be what is loosely (and falsely) called "exponential". Many doomsayers will complain that the institute is hopelessly optimistic. But the assumption is realistic for at least two reasons. Demographic history shows that sooner or later all communities learn how to balance births against deaths (and the doubling of world population in the next 50 years is less than the threefold increase in Britain between 1815 and 1865, when that demographic transition was more or less accomplished). The second reason is that those states that fail to keep their populations within bounds will end up in catastrophe. This is another plus for the institute.

So too is what the institute has to say about a number of other features of the business of energy forecasting. Technology will indeed make economic activity less energy-intensive than at present. Energy consumption per unit of Gross Domestic Product will continue to fall in developed countries as prosperity (Gross Domestic Product per head of population) continues to increase. And developing countries will not repeat the excesses of the states now industrialized, with the result that they will be able to attain (in half a century) prosperity not very different (outside Africa and South-East Asia) from that now taken for granted in Western Europe without ever having to consume more than 1 watt of energy for each annual dollar's worth of product. These assumptions obviously take the edge off the calculation of how supply and demand for energy can ever be matched. Once the need to worry about what will happen when developing countries consume energy as intensively as developed countries do now is done away with, the collective pressure on resources is diminished and the problem of supply and demand becomes manageable. This part of the institute's argument is well documented and well argued. Only those with a vested interest in believing that the worst will always happen will protest. So this is very much a plus for the institute.

How then does the future look? That is the question futurologists inevitably ask. Mercifully, the institute answers the question in the right spirit, thereby avoiding the snares which have trapped its predecessors. The flaw in most studies of this kind is that a scenario, while not a prophecy, is a hint of what may happen "other things being equal". The institute's study is more imaginative. The objective of a scenario, its study might have said explicitly, is not to show what the future will be like — for none of us can know — but to show that, on plausible and realistic assumptions, the future is possible. The problem, in other words, is to prove what the mathematicians would call an existence theorem. When that is done, extraneous influences — market forces for one, ingenuity for another — will do their work. And once, it has been demonstrated that getting from A (here) to B (there) is possible, it is best not to try to predict how it will be done. Apart from the safe prediction that for most of the next half-century fossil fuels (oil included) will continue to predominate, and from the guesses that global energy production will increase

dramatically in the next 20 years (by a factor of between 1.6 and 2.0) and fantastically (by a factor of between 2.6 and 4.2) by 2030, the institute gives few hostages to fortune. This is the good sense to be expected of a bunch of self-confessed natural scientists. Yet another plus for the institute, it will be concluded.

But how do we get from A to B? That is not a question in futurology, but a question for the present. What do we do now to make the possible future happen? The institute's report takes several novel and stimulating tacks. It has a cheerful account of the virtues of hydrogen as a convenient alternative to electricity as a secondary fuel (and urges that there should be more deliberate attempts to trap the hydrogen released from the deformation produced in the roots of plants in associations with nitrogen-fixing bacteria). The report is lukewarm but not frigid on biomass, futuristically open-minded about energy-collecting satellites in synchronous orbits and philosophical about nuclear power in both its forms — fission and fusion; it's a matter of time, and of giving people a chance to believe that those technologies can be made safely to work. Hurrah, it will be said; maybe there are several routes from A to B. That, for the institute, is a plus of a kind — perhaps half a plus. For these imaginative (but well written) parts of the summary report do not tell us what to do to get from A to B. Putting money into biomass (another name for wasteful forestry) or hydrogen research is only half an answer. For the truth about energy has become political, and will remain so at least until 2030.

Internationally, the proof that energy is a political matter came in 1969, with the *de facto* revocation by Libya of the licences it had earlier given to the multinational oil companies operating there; OPEC's resolve (in 1973) to put flesh on the bare bones of its long-declared intention to secure a fair share of the rent (in Adam Smith's sense) for its oil followed not long after. Domestically, until this year, the United States has been the worst offender, for political reasons charging too little for gasoline and other petroleum products, in the process giving its citizens the illusion that oil is rather like atmospheric oxygen — breathe in (exert demand) and the vacuum will be filled. President Reagan in the past two months has succeeded where his three immediate predecessors (Carter, Ford and Nixon) failed in deregulating the price of natural gas and crude oil in the United States. The short-term consequences have been dramatic — United States imports of petroleum have fallen to just over 3 million barrels of oil a day — 60 per cent of what they were two years ago. Even so, the prices of oil products in the United States are still less than elsewhere — no American administration, not even Reagan's, would risk a thoroughly free market (freedom for exporters and what that entails). The Americans, however, are only the worst and not the only offenders. The British, having found oil in the North Sea, are busily using the tax revenues arising as a poultice for persistent economic ills. Meanwhile, the moderation of OPEC in the past few months owes as much to the continuing war between Iran and Iraq, and the strengthening military relationship between Saudi Arabia and the United States, as to an explicit decision about the price oil can now command. Nobody is much concerned about Mr Willy Brandt's new-found constituency, the developing countries that happen to have no oil.

The institute's report acknowledges that such extraneous factors must influence the pattern of energy consumption in the decades ahead. Its good cheer is based on the assumption that people will behave rationally, on energy pricing, on the development of nuclear power, on a flexible strategy for research on alternative sources of energy, and in the avoidance of war. The caveats are sensible. It follows, however, that what the world now needs is not an existence theorem but a prescription for the avoidance of irrationality. By its nature, the Vienna institute is ill-equipped to help. Its members are, after all, predominantly natural scientists. *Energy in a Finite World* will bring credit to the institute — and would have brought more if it had seen the light of day some years ago. With the passage of the past eight years, however, the problem of energy has been transformed from one of technical analysis to a set of problems in politics, international and domestic. Who will provide the handbook for their solution?

Congress writes back Reagan economies

Democrats prepare for battle

Washington

Members of the US Congress are digging in for a period of extended skirmishing over Mr Reagan's proposed cuts in federal support for research. Democrats are already fighting to restore many of the cuts, and in the House of Representatives at least — where they still have a majority — have already had some success. In contrast, Republicans are sticking as tightly as they can to the fiscal surgery recommended by the Office of Management and Budget (OMB).

Last week, the science and research subcommittee of the House Committee on Science and Technology voted to authorize a budget of \$1,161 million for the National Science Foundation (NSF) in the fiscal year 1982, 12 per cent more than Mr Reagan's proposed budget of \$1,033 million. As expected the committee voted to restore funding for science and engineering education. Mr Reagan's budget proposed that NSF involvement in these activities be terminated; but the subcommittee has restored \$75 million, close to the figure proposed by Mr Carter. It also agreed to restore \$26.1 million for research in the biological, behavioural and social sciences, another target of Mr Reagan's pruning.

Not all the subcommittee decisions went in the same direction. The members also approved a recommendation from Mr Allen Ertel (Democrat) to eliminate \$12 million which had been allocated for NSF's new Ocean Margin Drilling Program, initiated last year as a joint venture with the oil industry. A similar proposal to eliminate ocean margin drilling activities made by the House last year was overruled later by the Senate.

The subcommittee's recommendations on the NSF budget now go to the full science and technology committee, which will decide whether or not they should be passed intact to the floor of the House and where further opposition from Republican committee members is expected. The previous enthusiastic support for NSF by the full committee is now less certain — some Democrats may vote with the Republicans (as they have already done to push through proposed reductions in earthquake research and other projects sponsored by the Federal Emergency Management Agency).

In the Republican-dominated Senate it is generally expected that action on the NSF authorization will be held to Mr Reagan's level. If so, the major debate will come when the House and the Senate meet to

reconcile their approaches. These proceedings could be repeated when Congress decides how much money it wants to hand over to NSF rather than just to authorize.

A similar confrontation is brewing over the budget for energy research. President Reagan proposes major cuts in support for research into alternatives to oil and fossil fuels, such as solar and geothermal energy and alcohol fuels, arguing that these will be encouraged by proposed tax credits and that demonstration projects represent a hand-out to the private sector; in contrast he has recommended a substantial increase in funding for nuclear energy.

House Democrats are trying hard to reverse these proposals, sometimes with the assistance of Republicans who accept the economic rationality of federal investment in energy-saving technologies. The energy development subcommittee of the House Science and Technology Committee has already voted to increase the solar research budget from the \$193 million proposed by Mr Reagan to more than \$500 million, closer to Mr Carter's figures.

This proposal, if sustained by the full House of Representatives and if the Senate sticks with Mr Reagan's policy, is again likely to create substantial conflict. Aware of this possibility, the Department of Energy is said to be drawing up new legislation which would dramatically reduce its responsibility for developing new and renewable energy sources.

Despite Republican predictions of economic doom should the budget cuts not be approved by Congress — and threats of a presidential veto in this eventuality — many individual researchers remain confident that congressional allies will help save their projects. One example is research

in magnetohydrodynamics (MHD), aimed at improving the efficiency of coal-fired power stations, on which more than \$400 million of government funds has already been spent.

In its budget proposals the Reagan Administration suggests that research and development on MHD, previously scheduled to receive \$60 million in 1982, be terminated, arguing that the demonstration of engineering feasibility should become the responsibility of the private sector. A senior OMB official explained that the agency had "agonized greatly" over whether to make the cut; but that although MHD research met two of the government's present criteria for support — high-risk research with a long lead-time — it did not meet the third — a high probability that any successes would be taken up by private utilities.

MHD engineers, however, claim that many utilities remain committed to MHD, which is predicted to increase the efficiency of electricity production from coal by 50 per cent. They point out that cuts at this stage would not make sense, as most of the money is required to cover the operation of two plants whose construction is nearing completion, at the University of Tennessee's MHD Coal-Fired Flow Facility in Tullahoma, and the Component Development and Integration Facility for which superconducting magnets are being provided through the Massachusetts Institute of Technology.

Officials in Tennessee said last week that they expected local congressmen such as Representative Albert Gore or Senator Jim Sasser to argue successfully that the funds should be restored. In other years, their confidence might have been justified. This year, with OMB defining demonstration projects in energy research as "the new

Hidden cheer culled from statistics

Washington

In a neat display of the power of statistics, Reagan Administration officials have estimated that, even with the proposed cutbacks, spending on basic research will increase in real terms in the fiscal year 1982. Figures prepared by the Office of Management and Budget, assisted by staff from the Office of Science and Technology Policy, predict that funds for basic research will grow by 1.5 per cent from the 1981 level. At the National Science Foundation, where the cuts have focused on science and education and social and economic research, basic research in the natural sciences would show 3 per cent real growth.

The catch to these otherwise heartening figures is that they are based on an officially-predicted inflation rate of 7.5 per cent — an optimistic forecast that

assumes almost instantaneous success for Mr Reagan's economic policy.

Overall, the Office of Management and Budget expects the research and development budget for 1981 to be "a few hundred million dollars" higher than the previously expected figure of £35,600 million, largely because cancellations in civilian research will be more than offset by a \$500 million increase in military research. The net result of Mr Reagan's proposals would be to increase research spending by about 13 per cent between 1981 and 1982, to a total of \$40,600 million. Compared with Mr Carter's proposals, the research budget for the Department of Defense would be increased by an extra \$1,500 million, while the non-defence budget would be \$2,200 million less than first proposed.

David Dickson

pork barrel", there is more doubt.

Last week, for example, even the chairman of the House science and technology committee, Mr Donal Fuqua (Democrat) failed to persuade the members of the energy supply subcommittee to support his efforts to reinstate funds for a synthetic fuels demonstration project which faces shutdown without further federal support. Other areas in which efforts to restore funds are being made are for the Ocean Thermal Energy Conversion programmes — OTEC — described by OMB officials as being of very limited pay-off — and the decision to hold back on establishing a Center for Fusion Energy and its Fusion Energy Device, both centrepieces of Mr Carter's plans for the rapid development of magnetic confinement fusion.

David Dickson

UK aerospace

Eager for orders

British industry is beginning to wake up to space communications as a commercial proposition. British Aerospace, the largest British company with a space interest, is on tenterhooks, waiting to hear whether it has won two major contracts for communications satellites. The orders at stake are for a British defence communications satellite network and for the Arab regional satellite communications system, Arabsat.

The contracts would be a watershed for the company, for it has hitherto had only the European Space Agency as a customer for satellite systems. If its bids are now successful, it hopes to compete for similar orders in other parts of the world.

Arabsat, which is also being contested by Ford Aerospace and the Hughes Corporation, is the most crucial of the two. British Aerospace is cheered that it has appeared on the short list of three out of the five initial bidders. The Arab countries are to make a decision within four or five weeks.

Competition for the defence satellite system is not so fierce. The British government, which had been expected to award the contract at the end of March, is taking its time choosing between British Aerospace and Marconi. The plan is to order three satellites, worth a total of about £100 million, one of which will be operational at any time and which will replace the seven-year-old Skynet satellite. The company that wins will hope to gain a foothold in the NATO market.

British Aerospace's attempts to become a major supplier of telecommunications systems have also extended to setting up joint ventures with other companies. Together with Plessey, which has built satellite earth stations, it says it can offer a team capable of building complete defence communications satellite systems. It is also planning a joint venture with the US Comsat General corporation to lease military satellite communications services. And its ambition to compete for more

contracts like Arabsat led it last month to set up a group called Satcom International with the French company Matra. Satcom plans to put in a bid for a regional satellite for Australia in May.

British Aerospace is selling itself on its experience. It has played a leading part in the telecommunications activities of the European Space Agency, having been the prime contractor for the series of Orbital Test Satellites and the more sophisticated European Communications Satellites. It also prides itself on being the only non-American company to contribute to Comsat General's Comstar programme for long distance telephony within the United States.

Attempts to exploit the commercial potential of space may have come rather late in Britain. But the present flurry of activity is not confined to aerospace and electronics companies. The Department of Industry says that an increasing variety of organizations, from banks to pension funds, now think of telecommunications when asking where to put their money.

How matters will develop depends not only on the industry's ability to compete and fulfil its promises but also on what the British government decides. The industry is now in limbo waiting for a government response to a confidential report by the Central Policy Review Staff on the commercial exploitation of space and for the publication of a Home Office report on direct broadcast television by satellite. The reports, if nothing else, may recommend making it easier for venture capital and private enterprise to take a share of the action.

Judy Redfearn

UK nuclear power

Battle begun

The first shots have been fired in the impending battle about the building of a pressurized water reactor (PWR) in Britain, even though the Department of Energy has not yet decided when the proposed public inquiry will be opened. Last week, the Friends of the Earth (UK branch) issued a document subtitled "A critique of the government's nuclear power programme" (Friends of the Earth, London; £1.50) which concludes that its

own case against the proposed reactor, to be built at Sizewell in Suffolk, on the North Sea coast, is so strong that a public inquiry is not necessary.

The argument is straightforward. First, forecasts of electricity demand in the United Kingdom, revised downwards for the past several years, are "wholly unrealistic" and are likely to be further undermined by changing patterns in the demand for electricity. Second, the cost of building the first British pressurized water reactor is likely to be twice the Electricity Generating Board's estimate (of £850 per kilowatt) while the cost of generating electricity will be magnified by the alleged low availability of reactors based on the Westinghouse design.

Third, the report (which includes a helpful account of the design changes required by the British nuclear inspectors) says that "the unique hazards of the American PWR must not be introduced into Britain". It is especially critical of a study by the nuclear inspectors of the generic safety of this type of reactor, which has not been published in full. The report also argues that "unresolved" problems concerning the safety of these reactors have not yet been resolved.

The conclusion is that Britain (and British taxpayers) would be better advised to put their money into renewable resources. Insulating lofts to a high standard would be six times as productive as building a pressurized water reactor at Sizewell, according to the Friends of the Earth.

Earlier this week, the Central Electricity Generating Board — the chief but not the only target of the Friends of the Earth — had not decided whether, and if so how, to reply to the criticisms levelled at it. To the extent that some of the complaints coincide with the criticisms of the House of Commons Select Committee on Energy some weeks ago (see *Nature* 19 February p.621), the authors of the new report may have to wait until the formal response from the Department of Energy.

The intended public inquiry about the proposal to build a single pressurized water reactor at Sizewell is now a formal commitment by the British government. Although the form of the inquiry has not yet been settled it is likely to be generic, dealing not with the characteristics of the Sizewell site

Magnox at Dungeness A — open soon?

but with the virtues (or lack thereof) of pressurized water reactors in general. Most probably, the inquiry will not now begin until the second half of 1982, implying that construction of the reactor system cannot begin until late in 1983.

For the electricity undertakings, the chief objective of the proposal to adapt an American design to British circumstances is the hope that pressurized water reactors could be built more quickly than indigenous gas-cooled designs. The Friends of the Earth document, however, is sceptical of the six-year construction time on which the generating board is counting.

Meanwhile, the Central Electricity Generating Board is somewhat encouraged that four of its oldest gas-cooled reactors, shut down some months ago after the discovery of cracks in the expansion joints of the gas-cooling circuits, can soon be started up again. The first of these reactors, at Berkeley on the Severn, is to be restarted in a few months following a demonstration that the cracks have not grown since the reactors were first built.

Czech nuclear power

Action on safety

Czechoslovakia's nuclear energy authorities have recently made overtures to their British counterparts, suggesting that the agreement on cooperation in nuclear safety, signed almost 15 years ago, should be revitalized. In particular, the Czechs are seeking an exchange of information and expertise on the disposal of nuclear waste and on the training of power station personnel.

The human factor in nuclear accidents has lately become a major concern in Czechoslovakia. Last August, after repeated denials, and without any attempts to prepare public opinion, the authorities suddenly admitted that in the past few years there had been two major accidents at the Jaslovské Bohunice nuclear power station.

During a recent phone-in programme on Prague radio, Dr E. Medke, director of the Nuclear Power Station Research Institute at Jaslovské Bohunice, described the institute's "high quality" research programme, aimed at the "long-term, safe, reliable and in particular, economically effective" operation of Czechoslovakia's nuclear power stations. This, he said, is to include work on the human element in safety. Analysis of nuclear accidents throughout the world, he said, shows that only 20 per cent were caused by equipment failure and the rest by operator error.

A training programme is under way to provide the 1,300 graduate engineers whom the country's nuclear programme will need by 1990. After taking a first degree in engineering, the candidate will go on to a two-year theoretical course, and then to a power station for practical

training. This will include work on a simulator, now being built at Trnava. After careful screening, the student will then become an assistant at a nuclear power station, and will finally take examinations set by the State Commission to qualify for a nuclear engineer's licence.

Czechoslovakia, which is more than self-sufficient in uranium, has a major commitment to nuclear energy, and accordingly tried to hush up the accidents at Jaslovské Bohunice, one of which involved two deaths. But in 1978 the Charter-77 movement published a detailed report on the incidents — and although then still unprepared to acknowledge that anything untoward had occurred, the authorities immediately inaugurated a policy of recruiting nuclear power station workers of a better psychological calibre — a major recommendation in the Chartists' report.

In the radio programme, Dr Medke made no mention of the accidents, and left his deputy, Dr S. Novak, to deal with public apprehensions about nuclear power. Regarding the station now under construction at Mochovce near the Hungarian frontier, Dr Novak said that there has never been a case in which one country has contaminated another's territory by nuclear effluent, and that all Czechoslovak power stations have adequate safety measures to prevent environmental damage in the case of breakdown or failure. This statement contradicts the Chartists' report which alleges that in one of the incidents at Jaslovské Bohunice, effluent reached a watercourse. It also contradicts claims from Bulgarian environmentalists that radioactive contaminants can be found in the Danube — although these are conventionally assumed to be of "capitalist" origin.

Vera Rich

Soviet space programme

Mongolia's turn

Last week's spaceflight of the Mongolian cosmonaut, Jugderdemidyn Gurrachaa, coincided with the start of the diamond jubilee celebrations of the Mongolian People's Republic. A few days before the launch, Mongolia's new Five Year Plan was published, extolling the value of science and technology to the development of the republic.

Not surprisingly, most of the experiments performed by Gurrachaa and his Soviet colleagues aboard the Salyut-6 were aimed at practical applications rather than basic research. One of the major tasks was the mapping of Mongolian natural resources, using conventional cameras and a Bulgarian "Spektr-15" multichannel spectrophotometer. This survey will provide data for existing joint Comecon research projects on Mongolian resources including the irrigation of the Gobi Desert. A programme of simultaneous photo-

Gurrachaa — applying science?

graphy of the Salyut spacecraft from Mongolia's two satellite tracking stations (in Ulan Bator and the Gobi) was intended to provide data on factors affecting space geodesy.

The biological programme involved the monitoring of the cosmonauts' biorhythms, work capacity, cardiovascular function and psychological response to the conditions of space travel. The biorhythm observations were started in 1977 during the selection of candidates for cosmonaut training — apparently the first time that a psychological and biochemical study of Mongolian citizens had ever been undertaken on a daily basis. Technological experiments included the study of natural quartz and of various alloys of copper under zero gravity.

Fundamental research was not completely ignored in Gurrachaa's mission. An experiment codenamed in Russian "Izlučenje" (radiation) continued the Mongolian work on primary cosmic rays with energies in the TeV range which was begun in 1972 with an experiment designed by S. Sugar and B. Chadraa of the Laboratory of High Energy Physics of the Academy's Institute of Physics for the joint Comecon Interkosmos-6 satellite in 1972.

Vera Rich

UK computer industry

ICL falters

International Computers Limited (ICL), Britain's largest computer manufacturer, announced last month that it has been trading at a substantial loss since the middle of 1980. The news of ICL's problems came only a few weeks after similar news from Imperial Chemical Industries (ICI). Until the beginning of this year, both companies had been regarded as profitable examples of Britain's otherwise ailing industry.

Unlike ICI, however, ICL is to be bailed out by government money. Sir Keith Joseph, Secretary of State for Industry, has said that the government will act as guarantor for up to £200 million worth of

loans which the company is expected to secure from the banks. Help is also to be provided for ICL's research and development programme which last year consumed about 8 per cent of the company's £715 million turnover.

Sir Keith's intervention is seen as a major blow to the Conservative government's policy of not interfering in private industry. But the decision was taken only after several months of searching for private investors had found no takers. The chief justification for supporting ICL when other private industries are allowed to go to the wall seems to be that the smooth operation of many government offices depends heavily on its computers.

ICL is something of a favourite of British governments. When it was created in 1968 from the amalgamation of two computer companies, the government retained a substantial shareholding and supported it heavily during its early years both with cash and with awards of almost all contracts for large computers for government departments. In the 1970s, the company became profitable and in late 1979, Mrs Thatcher's government sold off its shares. But only 18 months later, ICL's profits took a lurch.

Precisely why the company's fortunes changed so suddenly seems to be a mystery. The company itself says that the world recession combined with the strong value of the pound and high interest rates is responsible. There were hints of trouble, it says, in the first half of 1980 but during the second half both home and overseas orders fell off markedly. Others have said that poor management, a concentration on large computers when the market is moving towards desk-top machines, spending too much on parts of the business not connected with manufacturing and even underpricing goods, are also responsible.

Neither the government nor the banks, however, seem to have stipulated conditions for the £200 million loan. The company hopes to ride out the recession by continuing business much as before and economizing wherever possible. It says, for example, that its research and development programme will continue at much the same level as last year, with the same mix of research on large and small machines. One of the projects on which it pins hopes for the future is the large Distributed Array Processor which has so far been sold to the British National Oil Corporation, for seabed exploration, and Queen Mary College University of London. The Science Research Council is considering buying one for its Rutherford or Daresbury laboratories.

Sir Keith Joseph hopes that the government will not have to make good its guarantee, believing that the loan will see ICL through the recession until business picks up again. Meanwhile, the net is still being cast far and wide in the hope of finding private investment on suitable terms.

London medical schools

Mergers galore

The University of London has made a modest beginning on the reorganization of its twelve medical schools. Last week, the senate of the university approved a plan to save something like £5 million a year, or ten per cent of the present cost to the university of medical education. Some two-thirds of the saving will come from a general reduction of staff-student ratios throughout the medical schools.

The accompanying reorganization of the London medical schools is only a pale shadow of the grand design put forward more than a year ago by a committee under Lord Flowers, rector of Imperial College. At the senate meeting last week, it was formally agreed that the Westminster Hospital Medical School (a clinical school now recruiting about 100 students a year) should be merged with the medical school at Charing Cross Hospital (now located in West London). Other proposed groupings of medical schools have been given until later in the year to work out how they will coordinate their teaching.

The Westminster school considers itself unfairly singled out by these developments. Ever since the publication of the Flowers Report, Westminster has been urging the benefits of small medical schools, complaining that its students or their successors will be lost in a medical school with an annual intake of 180, the planning figure for clinical students at Charing Cross. It also says that the efforts that have been made in the past year or so to coordinate teaching between the two hospitals may be jeopardized by the shotgun marriage now decreed. Given forward commitments to students, it may be as much as five years before teaching comes to an end on the Westminster site.

In retrospect, the schools least affected by the changes now proposed are those at Guy's Hospital and St Thomas's Hospital, which announced last year that they would form a joint school, with a single governing body, but would continue to operate on both the present sites. This arrangement has now been sanctioned by the university senate. The other consortia from which the university is seeking financial savings are University College, Middlesex and St Mary's, which are required between them to save the equivalent of one clinical and one preclinical school; St Bartholomew's and the London Hospital, which have been given until June to suggest how they will merge; and King's College (which has a preclinical school) and King's College Hospital, which seem to be willing to fall in with the recommendation that they should form an integrated unit.

The proposals accepted last week by the senate were recommended by the Joint Planning Committee on Medical Education, set up to pilot the Flowers Report through the university. In the past

year, and especially as a result of a detailed analysis of the costs of the London medical schools carried out by a firm of accountants, it became clear that changes of staff-student ratios offered the most rapid route to cost reductions. The committee accepts as a standard for future staffing a ratio of 1:10 for preclinical schools and 1:7 for clinical schools. This would mean the loss of 180 academic posts, which it is hoped can be achieved by natural retirement and wastage in the next five or six years.

Running through the report of the joint committee is the view that medical education should be concentrated in larger units than at present, especially where modern buildings have been provided. In this spirit, the committee recommends that the development of the St George's Hospital site in South London should be continued. The future of the postgraduate medical institutes remains entirely open, however. With the exception of the Institute of Dermatology (which is to merge with St Thomas's Hospital Medical School), the institutes have been seriously affected by the reductions in the past year in the numbers of overseas students. The university is hoping that central government will help bail them out, but no decision has yet been reached.

Last week's decision by the university senate is likely to be regarded, within the University of London, as some kind of precedent for the reorganization of the non-medical parts of the university likely to be recommended by the Swinnerton-Dyer committee, due to report in September, and elsewhere as a sign that, if pressed hard, even British universities can change their ways.

Law of the Sea

US backtracks

Washington

The Reagan Administration's decision to carry out a complete review of the US position on the draft Law of the Sea Treaty, now under discussion at the United Nations in New York, indicates that significant new attitudes may emerge towards international resource disputes ranging from the surface of the Moon to the minerals of the Antarctic continent.

The United States is considering whether to adhere to the concept that natural resources which lie outside the immediate political domain of individual nations should be treated as "the common heritage of mankind" — a term coined by the United Nations — or whether, in the name of free enterprise and the national security implications of a shortage of strategic minerals such as cobalt and manganese, this concept should be abandoned, together with attempts to set up international regulationsto control exploitation.

A new twist to the Law of the Sea negotiations comes from the likely take-over of the Kennecott Corporation, a leading critic

of the United States' negotiating position, by Standard Oil of Ohio (Sohio). Sohio is 53 per cent owned by British Petroleum, which in turn is 45 per cent owned by the British government. In the past, BP Minerals, a member with Kennecott of one of the five consortia interested in deep-sea mining, has been keen to finalize the treaty to protect its existing exploration and mining operations.

In theory, a Sohio/Kennecott deal could favour a successful outcome to the Law of the Sea negotiations. In practice, the outcome could depend more on whether the Reagan Administration listens to arguments from international companies that a treaty is essential to the security of their future trading operations, or whether it gives greater weight to conservative pressure groups arguing that the whole "common heritage" concept, along with Third World demands for a "new international economic order", should be dismissed as socialist subversion.

In dismissing several key members of the US negotiating team, and initiating a complete review of the treaty in its draft form, the Reagan Administration is responding to complaints from groups such as the Council on Economics and National Security. Council officials were among the principal authors of a warning by the American Geological Institute to the two presidential candidates last September of a Soviet "resource war" aimed at depriving the United States of materials indispensable to its national defence.

Immediately after the election, the Reagan Administration set up a task force on national strategic minerals policy, which recommended a complete review of the draft Law of the Sea Treaty. One of the principal opponents of the treaty in its present form is a Washington attorney, Leigh Ratiner, acting head of the Department of the Interior's office of oceans and minerals under President Ford, and later the chief lobbyist on the treaty for the Kennecott Corporation.

Mr Ratiner is acting as counsel to the L-5 society, a 4,000-strong group of scientists and "futurists". The society is largely credited with stalling any effort by the Senate to ratify a draft treaty covering mining operations on the Moon, agreed in principle by the United Nations last year.

Particularly strong opposition to the treaty has been voiced by the US Steel Corporation of Pittsburgh, a leading partner in the Ocean Mining Associates consortium. According to the chairman of US Steel, William R. Roche, policies pursued by the Carter Administration tended to increase the country's strategic mineral vulnerability.

Attempts to scuttle the Law of the Sea negotiations have been fiercely attacked by Mr Carter's chief negotiator Mr Eliot Richardson, ex-ambassador to the United Kingdom, who warned that many multinational companies would face severe consequences if they tried to disrupt

agreements that had already been reached by US negotiators in good faith.

Many conservatives, however, see Mr Richardson's position as symptomatic of a "soft" approach to the Third World that does little to protect US economic and strategic interests. A change in strategy on the Law of the Sea Conference could also have implications for other negotiations.

Following the Antarctic Treaty of 1959, the 12 (now 14) nations laying claim to Antarctic territory have agreed voluntarily to restrain mining activities until an appropriate international treaty can be worked out. Yet this too is now being challenged by conservatives within the Reagan Administration, largely on the grounds that negotiations could result in the United States gaining less than it might expect from an international free-for-all, given its superiority in mining technology.

Delegates attending the Law of the Sea negotiations session in New York, although dismayed with the Reagan Administration's position, have agreed to

discuss the details of the draft treaty. Some had hoped that the Kennecott/Sohio deal, together with the influence of other international groups such as Royal Dutch Shell, might help to dilute the pressure of more nationally-oriented companies on the Reagan Administration.

Meanwhile, a group of lawyers, scientists, environmentalists and economists has issued a report calling for research into the character of the marine environment of the deep ocean, and its susceptibility to mining operations. The group points out that no explicit mention is made of the need for prior environmental assessment either in a bill on deep-sea mining rights passed recently in West Germany, or in draft bills now before French and British legislatures. It was also concerned that such nations might get together with the United States and other countries to set up their own institution for regulating mining activities before the Law of the Sea negotiations finally break down.

David Dickson

India mines the sea

New Delhi

India has become the first developing country to collect polymetallic nodules from the ocean floor, a distinction achieved by India's first research ship, the *Gaveshani*. The 1,900-tonne vessel, once a hopper barge and converted into a research ship in 1975, is operated by the National Institute of Oceanography (NIO) in Goa, one of the 40 institutes under the aegis of the Council of Scientific and Industrial Research.

NIO has been preparing the *Gaveshani* for nodule hunting since 1978 and the catch was made in January during her cruise from Goa to Mauritius, which was led by Dr S.Z. Qasim, director of NIO.

According to Dr Qasim, the *Gaveshani* located a nodule-rich region in the Indian Ocean about 700 miles from the mainland and reaching almost as far as Mauritius. During the return journey the ship collected more nodules from several locations at depths of 3,600–5,400 metres.

Besides nickel, cobalt, copper, manganese and iron, the samples are believed to contain traces of gold, but their precise metallic contents are now being analysed by eight Indian laboratories.

The *Gaveshani*'s nodule collecting gear

consisted of a 10,000-metre winch, underwater camera, dredges and some twenty "boomerang grabs", which go down to pick up the nodules and come up automatically. According to Dr Qasim, the surveyed seabed area had a nodule concentration of 1 to 5 kilogrammes per square metre, which is potentially economic for mining.

India is not ready to start mining proper, but NIO plans to map the nodule-rich region to assess its total mineral wealth. The operation should be speeded up next year when the *Gaveshani* is joined by a second research ship now under construction in West Germany. Since India imports all its nickel and cobalt and more than 60 per cent of its copper requirements, the discovery of a nodule basin in its close vicinity should be welcome news.

There is a long haul between picking up a few seabed nodules and being able to mine them commercially. Yet the *Gaveshani*'s demonstration has raised some eyebrows among nations that at present have a monopoly on ocean mining. It is likely that United Nations talks on the Law of the Sea will acquire a new dimension as a result of India's unexpected entry into the ocean mining club.

Hospital, London EC1, UK

Weed control

SIR — As May emphasizes¹, all possible steps should be taken to prevent the intrusion of noxious weeds into new regions. That article paid rather less adequate attention to weeds that are already established. Consider two hypothetical situations. Suppose it was discovered that one of these weeds contained a valuable fibre. Within a few years we would have a conservation programme to save the weed from extinction. Suppose enterprising adolescents found that one of the weeds contained a hallucinogen. The \$15 million quoted as the annual cost of water hyacinth control in Florida and Louisiana would be "chicken feed" compared with what drug control authorities would spend on elimination.

Water hyacinth has been studied for so long that components as dramatic as these are unlikely to be found in it. Nevertheless, it is a prodigious producer of biomass and is often conveniently located on broad areas of water from which mechanical collection is easy. Twenty one years ago² I made "... a plea for some reorientation of thinking in areas suffering from, or threatened with, water hyacinth. There is a case for directing some research towards finding uses for the pest instead of concentrating all efforts on its eradication."

Since then, the pest has made great headway. Less headway has been made on finding uses for it. Interest is, however, increasing. Chibbar and Singh³ fed cows on silage made from water hyacinth and paddy straw, and there have been several recent papers in the *Indian Journal of Animal Science* extending that work. Hyacinth is deliberately cultivated in China for pig feed. It is a component of the mixtures used for biogas fermentation in many countries. These and other uses are surveyed in *Making Aquatic Weeds Useful* (US National Academy of Sciences, 1976) and in *Handbook of Utilization of Aquatic Plants* (Food and Agricultural Organization, 1979). This is encouraging. But the amount of effort put into finding uses for water hyacinth and other weeds is a tiny fraction of the effort put into killing them. I do not suggest deliberate encouragement, only the assignment of comparable importance to both lines of approach.

Cafeteria feeding

SIR — I wonder if I am alone in my dislike of the term "cafeteria feeding" used first, I think, by Rothwell and Stock in 1979 (Rothwell, H.J. & Stock, M.J. *Nature* 281, 31; 1979). According to the *Concise Oxford Dictionary* a cafeteria is a "restaurant in which customers fetch food and drink from a counter" which is hardly an accurate description of the behaviour of rats allowed to make their own choice of palatable items of food. I would like to suggest that, before it is too late, editors of scientific journals ask authors to use a more accurate description, for example to replace "cafeteria diet" by "a self-selected palatable diet" (abbreviated SSPD) or other equivalent term.

Cancer causation

SIR — The recent series of articles¹⁻³ on cancer causation prompts me to respond. Without defending Epstein and Swartz, I would like to offer several alternative explanations to some of the examples which Cairns used to argue his case that somatic mutations play little or no part in human carcinogenesis.

Although Cairns' novel hypothesis is to be welcomed as a stimulus to new experimental approaches, I feel that he has summarily dismissed a significant amount of evidence consistent with the somatic mutations theory of cancer. Furthermore, carcinogenesis is a multi-step process and there are probably several distinct molecular mechanisms that can "cause" and influence carcinogenesis, not the least of which are somatic mutations⁴.

Specifically, Cairns argues that the *apparent* lack of common fatal cancers in xeroderma pigmentosum (XP) individuals (the cells from whom lack proper DNA repair causing them to be hypermutable to many mutagens, including the ultraviolet component of sunlight) is evidence that the production of mutations in XP cells is probably irrelevant to carcinogenesis. There are at least two reasonable alternative explanations why XP patients rarely get cancers other than skin tumours⁵. The XP patients normally do not live long enough to manifest these internal tumours (an explanation cited but dismissed by Cairns) and most cancers are the result of initiation (mutagenesis) and promotion (amplification of an initiated cell into a clone where additional genetic or epigenetic changes can occur). One can explain the production of skin tumours in XP on this hypothesis since, using this concept, repaired sunlight-induced lesions in the skin cells of XP patients will lead to both cell killing and mutated viable cells.

In effect, the large numbers of killed cells will "force" the surviving, but initiated, cells to repopulate the necrotic tissue, giving rise to clones of dysfunctional cells. During that repopulation phase, some of these initiated cells are further exposed to more mutagens. Thus, the cytotoxicity caused by the inability to repair large amounts of sunlight-induced DNA damage can be considered an "indirect promoter", much in the manner of a partial hepatectomy⁶. On the other hand, internal cells of XP patients, which are exposed to

chemical mutagens that mimic sunlight-induced DNA damage, probably are not exposed to high enough levels constantly to cause significant cell killing, as occurs in the skin. In effect, these initiated cells will not be promoted! Only after long periods of time or exposure to chronic effective levels of exogenous or endogenous tumour promoters will internal tumours appear.

A second argument used by Cairns to support this thesis of genetic transposition was the discussion on Bloom's syndrome. I agree with Cairns that Bloom's syndrome might be a "better" model for studying carcinogenesis, but for a different reason. At the time of writing his paper, Cairns was not aware of the observation that Bloom's syndrome seems to be a "mutator" syndrome⁶, in that it spontaneously generates mutations in their somatic tissue. In effect, Bloom's cells can generate mutations in any proliferation cell of the body, with or without exposure to "environmental" mutagens. This would explain the wide range of tumours (and other clinical features) associated with the syndrome, and would also fit the initiation/promotion model, since each time a spontaneous mutant cell arises and then divides, it can enhance the probability of additional genetic imbalances.

Genes and free will

SIR — Asked to dissociate themselves from the neo-Nazi use of their names and theories, John Maynard Smith¹ and Richard Dawkins² have both done so. Professor Maynard Smith's unequivocal couple of sentences will be no surprise to scientists who know him as a man of principle and integrity; his letter will give no comfort to the National Front or any similar grouping.

It is a pity, though, that Dr Dawkins appears to think that the issue I sought to raise in my letter is of a parallel with the relatively harmless debate on cladistics and dialectics which has kept us entertained over recent months. If it were not for that dreary little edge of "reds under the bed" of which Stephen Jay Gould reminds us³, I suspect we could look forward to *Nature* with the same enthusiasm as once we had for *Beano*. However, the issues are not the same. Racism directly haunts the streets of our cities. In our laboratories neither Dawkins nor I live in the daily hazard that the obscene rubbish of the *New Nation* and its followers fosters in the East End or New Cross. When Dawkins disdains the ephemera of mere "human politics", or accuses his critics of being as guilty as the Nazis of dragging the elegant purity of his neo-Darwinism into the litter of the city streets, he does so at the peril of a repetition of the tragedies of the 1930s.

Of course we must all beware of the fallacy

NEWS AND VIEWS

Nerves, myelin and multiple sclerosis

from Miranda Robertson

At the beginning of December, a select group of clinicians came together with a similar group of research biologists in Berlin to plumb the depths of their respective ignorance about multiple sclerosis and the glial cells of the central nervous system. Multiple sclerosis is baffling in almost every respect — its cause is unknown, its pattern erratic and its course extraordinarily variable. The target of the disease is the myelin that insulates the nerve fibres of the central nervous system, or the oligodendrocytes that produce it. The symptoms are thus due to blocked or unreliable conduction along nerves, but it is not known what induces the attack on the myelin; nor is it understood why, rather than steadily worsening, the symptoms should alternately flare up and partly subside over the progressive course of the disease; nor why some patients may remain free of symptoms for years after a first attack, whereas others will suffer repeated relapses and die within a decade.

Two of the principal aims of the meeting*, whose main topic was the relationship between neurones and glia but which also included much discussion on viral and immunological mechanisms, were to try to establish, first, what is going on in multiple sclerosis patients, and second, what might be done about it.

Probably the most cogent view of the characteristics of the disease is due to the immunologists, whose contribution has recently been discussed in *Nature* by Bloom¹. The pattern of exacerbation and remission of symptoms, for example, may represent defective (and thus irregularly oscillating) regulation of an immune response, manifesting itself as recurring episodes of inflammation — an explanation consistent with the efficacy of steroids during acute attacks (B. Arnason, Chicago University).

The cause of the inflammation and tissue

destruction could be a latent virus infection and the immune response to it, or an autoimmune attack on the central myelin that might or might not have been stimulated in the first instance by viral infection. In animals, the pathological changes can be mimicked by some viral diseases, or by immunization with central myelin — though in the latter case, the disease follows a chronic relapsing course only in animals with genetic immune deficiencies. (This may be significant in the light of evidence in man for linkage with specific HLA antigens: see below.)

However, multiple sclerosis itself is not associated with a specific immune response either to a particular virus or to a component of the central nervous system; nor is there any evidence that immunosuppressive treatment can alleviate acute attacks of the disease. This raises two questions. The first is that of the relevance of any of the existing animal models to the human disease. The second is whether there is any point in looking for immune correlates of multiple sclerosis without having identified a specific antigenic target: immune activity in itself is a very poor guide to aetiology, since tissue degeneration from any cause (including, for example, stroke) will attract the attention of the immune system.

Nonetheless, many laboratories have looked for changes in the immune response that may be associated with multiple sclerosis, and one of the most recent fruits of such research has been the discovery that exacerbations of the disease coincide with a reduction in the level of circulating immunoregulatory T cells². This may mean that the failure of immune regulation unleashes the attacks (in which case, however, why specific to central myelin?), or alternatively that suppressor T cells and oligodendrocytes share an antigen and the disappearance of the immunoregulatory lymphocytes is a concomitant and not a cause of the attack. Many participants at the meeting took the view that the latter was the more interesting possibility

because it could lead to the identification of the antigenic target — an advance whose importance it would be hard to exaggerate.

There is, of course, a strong possibility that there is no single cause of multiple sclerosis. It was generally agreed, for example, that if the disease is a response to viral infection it is very likely that more than one virus can elicit it. But some very preliminary genetic evidence suggests that the heterogeneity of multiple sclerosis may run deeper than that. Nowadays, if nothing else is known about a disease — in fact, particularly if nothing else is known — its HLA association is. Multiple sclerosis in Europe is in linkage disequilibrium with HLA antigens D2 and D4 (ref. 3), but more recent investigations have revealed a further link, with DR3. The significance of these associations is unknown, but their weakness, together with genetic evidence from family studies, and in particular from twins, strongly suggest that HLA D2 and D4 are in linkage disequilibrium with some other, unknown genetic factor predisposing to the disease (W.I. McDonald, London University). The case of DW3, on the other hand, may be different: DW3 is associated with two known autoimmune diseases, myasthenia gravis and autoimmune thyroiditis; there is thus a possibility that its prevalence reflects a defect in immune regulation predisposing to autoimmune attack — the exact target presumably depending on other factors.

If the ultimate cause of multiple sclerosis remains unknown, can anything be done in the meantime about its proximal cause? Can conduction be restored in demyelinated nerves, or dead oligodendrocytes be replaced? Drugs that enhance conduction have been tried, but without much success. One of the most recent efforts in that direction has been with 4-aminopyridine, which blocks potassium channels and prolongs the action potential⁴. This facilitates

Miranda Robertson is an associate editor of *Nature*.

*The Dahlem Conference on 'Neuronal-Glial Cell Interrelationships' was held in Berlin on November 30–December 5 1980. A Dahlem Workshop Report on the conference will be published.

conduction but unfortunately at the same time promotes seizures. It is, in any case, doubtful how far simply overcoming conduction block could restore useful function, since both the pattern and the spread of impulses would inevitably be grossly abnormal.

Some natural short-term recovery of function, on the other hand, is to be expected on the basis of recent investigations on the distribution of sodium channels in myelinated nerves. In the peripheral nerve, sodium channels are clustered at the nodes of Ranvier, being scarce or absent in the membrane under the myelin sheath⁵. This means that immediately after the demyelination of a peripheral nerve, conduction is completely blocked and it is not until some days afterwards that sodium channels begin to appear at the internode region and action potentials can be propagated across it (T.A. Sears, London University). If the same differential distribution of channels holds in the central nervous system (and there is some evidence that it does⁶), the exacerbating and remitting pattern of multiple sclerosis may partly reflect the

length of time it takes for sodium channels to redistribute themselves after demyelination.

Real recovery could be brought about only by the proliferation of oligodendrocytes and remyelination of axons. Although Schwann cells are known to proliferate and remyelinate peripheral fibres, and central remyelination commonly occurs in other demyelinating diseases, it does not seem to occur in multiple sclerosis. This suggests that multiple sclerosis may destroy the oligodendrocytes which, unlike Schwann cells, cannot be replaced. This reflects the more advanced state of differentiation of the oligodendrocyte. Not only can Schwann cells in culture be induced to proliferate, both by contact with axonal membrane (R.P. Bunge, Washington University) and by a soluble pituitary protein⁷, but they can also be induced by co-culture with nerves to increase 1,000-fold the synthesis of the principal myelin protein; or, by co-culture with muscle cells, to synthesize acetylcholine. Cultured oligodendrocytes, on the other hand, will synthesize the principal central myelin proteins in the absence of

neurones, although they do seem to depend on astrocytes to support proliferation (R. Mirsky, London University). What signals either Schwann cells or oligodendrocytes *in vivo* is quite unknown, although with the recent development of specific markers for central and peripheral neurones and glia, this question is now open to investigation *in vitro*.

Whether such investigations will make any direct contribution to the treatment of multiple sclerosis, or whether the capacity for recovery in the central nervous system lies in its inherent plasticity rather than in regeneration, only more research can show. In the meantime, everyone agreed that prevention is always preferable to cure; in the case of multiple sclerosis, it may be the easier to achieve. □

A new model for phototransduction

from Peter G. Lillywhite

IN this issue of *Nature*, R. Payne and J. Howard (see page 415) put forward a new model for phototransduction which provides an elegant alternative to the cascade model of Hodgkin¹. A successful model for phototransduction in vertebrates and invertebrates needs to explain (1) the latency of the response, (2) the increase in sensitivity to light steps and flashes with dark adaptation, and (3) that large increases in sensitivity can occur with only small changes of time scale. In the model invented by Hodgkin and fitted to *Limulus* receptors in collaboration with Fuortes¹, a cascade of stages, each occurring with an exponential delay, was assumed. Several stages are required because a single step would not, for example, exhibit latency. It turned out that about ten exponential stages were required to mimic the responses of *Limulus* receptors. Strong illumination was assumed to decrease the time constants of most, but not all of the exponential stages of transduction, causing the decrease in sensitivity observed with light adaptation.

It was immediately attractive to give physical reality to the hypothetical chain of exponential stages or 'events' as chemical reactions. Borsellino *et al.* showed in 1965 that, if it is assumed that the time constants of the exponential delays represent the rates of chemical reactions, the effect of temperature upon voltage response fits the classical Arrhenius relationship². Although they took the necessary precaution of pointing out that consistency

with the Arrhenius relation was not proof that the hypothetical chain of chemical reactions actually existed, chemical reaction chain models are nevertheless highly popular. For example, Baylor *et al.* recently (1974) modelled the responses of cones in the turtle retina using a chemical reaction cascade model³.

Payne and Howard now propose an alternative mathematical and conceptual model to that of Fuortes and Hodgkin and other similar cascade models. The model is attractive, because it describes locus photoreceptor responses (which are very similar to those of *Limulus* modelled by Fuortes and Hodgkin) almost perfectly, accounting for the three characteristics listed above, but does not require a chain or cascade of many hypothetical stages. The cascade models of Fuortes and Hodgkin and Baylor *et al.* have an unattractive side to them, which is the large number of implied transduction steps or reactions. To fit the photoreceptor responses they studied, Fuortes and Hodgkin required about ten steps and Baylor *et al.* required nine (six for creation and three for destruction of ion channel blocking particles). When Payne and Howard tried to use these models to fit locust photoreceptor responses, between 13 and 20 (Fuortes and Hodgkin model) and between 20 and 48 (Baylor *et al.*'s model) steps were required — a seemingly implausible number. Payne and Howard's

model is simple and minimal in its complexity and assumptions: photoreceptor impulse responses are assumed to be logarithmically transformed Gaussians. The only variables are s , the sensitivity, which is fixed for a given cell, and μ and σ , the mean and standard deviation of the transformed Gaussian. Furthermore, the effect of light adaptation and temperature change can be modelled by changing a single parameter, μ , which changes the time scale of the response and could represent the rate constant of a single transduction process.

Mechanistically, as well as mathematically, the Payne and Howard model is a simple working hypothesis which fits available data and is strikingly similar to recent suggestions by Hamdorf and Kirschfeld⁴ arising from their experiments on fly photoreceptors. Payne and Howard assume that absorption of a photon by a rhodopsin molecule leads to release of a chemical transmitter, the concentration of which smoothly rises to a peak before declining. The transmitter molecules open the ion channels responsible for the change in membrane potential during illumination. In insects and those other invertebrates which have rhabdomeric photoreceptors, illumination causes depolarization. However, in order to adapt this model to vertebrate ciliary photoreceptors, which hyperpolarize during illumination, one need only assume that the transmitter molecules close, rather than open ion channels. The threshold transmitter concentration for activation varies

Peter G. Lillywhite is Lecturer in Zoology at Sheffield University.

from one ion channel to another according, it is assumed, to a gaussian distribution. This variability is responsible, according to the Payne and Howard model, for the long-lasting nature of the membrane potential produced by an instantaneous light pulse. The long latency of phototransduction, which can be tens of milliseconds for small responses in dark-adapted receptors, is assumed to be due to the time required for transmitter concentration to exceed the activation thresholds of the ion channels. Hamdorf and Kirschfeld recently pointed out that the rapidity of micro-spectrophotometrically observable pigment conversion (around 0.5 ms) and diffusion cannot account for the long latency of phototransduction in flies. In showing that simultaneous absorption of two photons by the same rhabdomere microvillus causes a discrete reduction in latency, Hamdorf and Kirschfeld concluded that each rhabdomere microvillus may represent a single functional unit, which generates transmitter molecules by means of a single enzymatically activated transduction step⁴. As in the Howard and Payne model, Hamdorf and Kirschfeld attribute the long latency to the time taken for the concentration of transmitter generated to exceed a threshold level.

An additional requirement for any realistic model of transduction in insects is that the first 3–5 ms of transduction latency consist of reversible events localized at the level of the photopigment molecule, since Hamdorf and Kirschfeld have recently shown that reconversion of metarhodopsin to rhodopsin within this period prevents the rhodopsin to metarhodopsin conversion having any effect⁵. Thus, no irreversible events, such as release of 'live' transmitter, occur in this period. It is attractive to assume that the remaining few milliseconds before onset of the response are indeed due to a single enzymatically activated generation of transmitter, as suggested by Hamdorf and Kirschfeld⁴ and as fitted by Payne and Howard's mathematical model. No transduction enzyme has yet been fully characterized, although there is some evidence that a specific protein is involved in the intermediate steps of phototransduction⁶.

It would be interesting to know how well the Payne and Howard model fits the responses of other invertebrate photoreceptors and whether it can be used to model the responses of vertebrate photoreceptors, because it predicts a much simpler model of transduction than the reaction chain hypotheses. □

Second sound in ³He

from P. V. E. McClintock

SECOND SOUND is an unusual type of propagating wave mode, which can occur in superfluids, involving fluctuations in the local temperature and entropy of the medium rather than in the local density and pressure as found in a conventional sound wave. The phenomenon has been investigated, both experimentally and theoretically, in the common helium isotope, ⁴He, over many years; but its observation in ³He, whose ultra-low temperature superfluidity is still a relatively recent (1972) discovery, was reported for the first time by Corruccini and Osheroff only last year (*Phys. Rev. Lett.* **45**, 2029).

At temperatures not far below their superfluid transitions (~ 2 K for ⁴He, 2 mK for ³He), both liquid heliums behave much as though they were composed of two separate but freely interpenetrating liquids: a superfluid component (anisotropic in the case of ³He) with no viscosity or entropy and a normal fluid component possessing the properties of a (fairly) normal liquid. This type of two-fluid system is able, in principle, to support two quite distinct wave modes. Where the two components vibrate in unison with each other, the result is an ordinary density wave known as 'first sound'. If, on the other hand, the two components move in antiphase, with the overall liquid density remaining essentially constant, the characteristic wave propagation velocity turns out to be quite different, corresponding to 'second sound'.

Although second sound is very readily generated and detected in superfluid ⁴He, calculations had suggested that the corresponding mode in the principal (A and B) phases of superfluid ³He would travel exceedingly slowly and be very strongly attenuated as it travelled through the liquid. Consequently, although second sound should, in principle, exist in ³He, it would quite probably prove impossible to detect it in practice. Liu predicted (*Phys. Rev. Lett.* **43**, 1740; 1979), however, that within a very narrow region of the phase diagram, the A₁ phase, the liquid might, in fact, be capable of supporting a freely propagating second sound wave — and it would be second sound of an entirely novel and particularly interesting kind.

The A₁ phase is formed under the influence of a strong magnetic field as an intermediate stage in the transition between normal liquid ³He and the superfluid A phase. The superfluid component of the latter can itself be considered as being made up of two sub-components in which the constituent pairs of ³He atoms lie with their nuclear magnetic moments lying either parallel or anti-parallel to an applied magnetic field. These 'up-spin' and 'down-

spin' superfluids seem, in many respects, to behave almost independently of each other. When normal liquid ³He is cooled in a magnetic field, the superfluid transition to the A phase is found to take place in two stages, at temperatures T_{A1} and T_{A2} whose separation is proportional to the applied field, and this is believed to correspond to the two superfluid sub-components having slightly different transition temperatures. Thus, for temperatures in the narrow range (typically 50 μ K) between T_{A1} and T_{A2} , only one of the spin species will be superfluid — this is known as the A₁ phase.

Liu pointed out that second sound in the A₁ phase, if it occurred, would carry an associated magnetic disturbance: counterflow of the normal and superfluid components would necessarily involve a spin density wave because only one preferentially aligned spin species would be present. He was able to predict that, for a hybrid second sound wave/spin density wave of this nature, the velocity would be much higher and the attenuation much smaller than would otherwise be anticipated for second sound in ³He.

It is this hybrid wave mode whose existence Corruccini and Osheroff have now successfully demonstrated at the Bell Telephone Laboratories, Murray Hill. They generated the mode by vibrating a capacitatively coupled porous membrane in the liquid. The precise mechanism by which this type of transducer operates is still somewhat ambiguous but, if one assumes that the membrane couples only to the normal fluid component, it is then clear that any motion of the membrane will result in a relative velocity of the normal

P. V. E. McClintock is in the Physics Department at the University of Lancaster, UK.

and superfluid components. The primary detection system depended on the same principles, but operating in reverse.

The received signals were weaker than anticipated, but yielded velocities which, as shown in the figure, appear to be in excellent agreement with the prediction, based on the theory of Liu, that the square of the velocity should be directly proportional to the reduced temperature ($1 - T/T_A$). Some highly significant additional information was obtained from a small NMR coil placed in the middle of the experimental cell, which enabled the authors to monitor the magnetic disturbance which occurred as the second sound wave passed by on its way from the generator to the detector. On the basis of

careful analysis of the relative shapes of the NMR and acoustic signals they tentatively conclude that, quite contrary to expectation (Levin *Phys. Rev. Lett.* **34**, 1002; 1975), the paired spins forming the superfluid in the A_1 phase are in reality aligned 'up' along the magnetic field, rather than 'down'. This conclusion should be treated with caution until corroborated by some other means, but it is certainly intriguing.

Although several features of the experimental results still await detailed interpretation, there now seems no doubt that Liu's exotic wave mode exists in reality and that the work will lead to a significantly enhanced understanding of superfluid ^3He . $\square$

Ice core studies: dating the past to find the future

from W. Dansgaard

How did atmospheric carbon dioxide influence the climate in the past? Will the two large ice sheets, in Antarctica and Greenland, be stable enough to withstand a possible climatic warming? If not, how fast could they disintegrate? How old are they? How abrupt was the termination of the last interglacial, the Eem? When did it happen, and why? Did volcanic activity trigger that event? Is the Earth ripe for another catastrophic turn into glacial conditions? How did cosmic radiation change in the past? What were pre-industrial deposition rates of the various chemical elements that are now being emitted by modern industry?

These, and many other important problems may be partially, if not completely solved by investigation of the more than 3,000 m thick ice sheets which are proving richer sources of information about past atmospheric conditions than any other sequence of Quaternary sediments on Earth. All kinds of fall-out from the atmosphere, such as air-borne continental dust and biological material, volcanic debris, sea salts, cosmic particles and cosmic ray-produced isotopes, are deposited on the surface along with the snow and each year a new layer is added to the old. The snow pack is gradually compressed into solid ice with small cavities containing samples of atmospheric air. In the coldest areas of the ice sheets, the impurities remain in the ice as deep-frozen indicators of the chemical composition and the physical condition of the atmosphere at the time of deposition. Nothing is added, nothing runs off or is displaced, and no chemical reaction takes place; in fact, the composition of the ice layers changes only

by decay of the radioactive impurities and by extremely slow diffusion processes in the ice crystal lattice.

The ice layers sink into the ice sheet in an undisturbed sequence with continuous horizontal stretching and consequent thinning. In areas with no melting at the bedrock, the layers approach zero thickness close to the bottom. This is the reason why an ice core drilled through the coldest part of Greenland ice sheet makes it possible to establish continuous and detailed time series of many geophysical-chemical parameters, reaching several hundred thousand years back in time: CO_2 content in the atmosphere^{1,2}; climatic changes in terms of surface temperature³⁻⁵ and accumulation variations⁶; chemical composition of the atmosphere⁷; volcanic activity and its cooling effect in the troposphere⁸ and cosmic radiation flux¹. In central East Antarctica the oldest ice may even be an order of magnitude older than in Greenland, but the snow accumulation rate is so low⁹ — in some areas even zero or negative — that an Antarctic ice core does not necessarily represent a continuous sequence of deposition.

Dating of an ice core is prerequisite for proper interpretation of a data series. A number of dating methods have been developed on the basis of ice flow models, and analyses of isotopes, volcanic debris and continental dust in ice cores¹⁰. Most accurate are the stratigraphical methods, that is, detection and counting of the individual annual layers downwards from the surface. In areas with high accumulation ($> 25 \text{ cm ice yr}^{-1}$) and no melting, these methods allow absolute dating to within a few years per thousand if the ice core is in perfect physical condition. This

accuracy is required when high-frequency components of the time series are to be compared with similar features in other time series. For example, the acidity of annual layers could be reconciled with historical records of volcanic eruptions within the past millennium⁸ only because each layer was dated back to near the correct year of deposition¹⁰. So far, no ice core has been absolute-dated beyond AD 553.

Under favourable conditions the annual stratification will probably be detectable far beyond 10,000 yr BP, but, at present, ice from the early stages of the last glaciation must be dated by radioisotopes. However, the conventional low-level β -counting technique requires preparation of much larger amounts of ice than is available in an ice core¹¹. It is therefore a great step forwards that the limit of radioisotope detection has been lowered by orders of magnitude in recent years by means of an accelerator/mass spectrometer combination that identifies and detects the radioactive atoms themselves instead of the β -particles emitted when they decay¹²⁻¹⁵.

This makes it possible to perform ^{14}C dating back to 50,000 yr BP using as little as $1 \text{ cm}^3 \text{ CO}_2$ which is the approximate CO_2 content in 5 m of a 10 cm ice core. This core length may span only a few hundred annual layers at depths corresponding to 50,000 yr of age in the central parts of the large ice sheets¹⁶. Ice from the early stages of the last glaciation has to be dated by longer-lived isotopes, of which ^{36}Cl is the most promising. As the half life is relatively favourable (310,000 yr), a ± 3 per cent detection accuracy is within reach¹⁵; and an 0.5 m core increment is sufficient. Yet, the corresponding dating uncertainty will be as high as $\pm 13,000$ yr, even if the production rate of ^{36}Cl in the atmosphere is assumed to have remained constant. If the production rate at the time of deposition were 10 per cent different from the present value, it implies a dating error of no less than 43,000 yr.

This difficulty may be partly overcome if the ^{10}Be (half life 1.5×10^6 yr) concentration is measured in the same ice. The ^{36}Cl to ^{10}Be concentration ratio may then be used as an age indicator that is essentially independent of the production rate, because both isotopes are produced in the atmosphere by impact of cosmic radiation, and both of them are scavenged by precipitation after a short residence time in the atmosphere¹. Nevertheless, when accounting for another 3 per cent uncertainty on the ^{10}Be analysis, we end up with a total dating uncertainty of $\pm 30,000$ yr on an individual ice sample. Owing to the small amount of ice needed, it may be feasible to carry out independent datings on, say, 10 ice core samples of approximately the same age around 100,000 yr, thereby reducing the statistical uncertainty on the mean value to $\pm 10,000$ yr, which can be extremely useful for checking the validity of ice flow models. A complete $^{36}\text{Cl}/^{10}\text{Be}$ profile along the lower part of an

W. Dansgaard is in the Geophysical Isotope Laboratory of the University of Copenhagen.

ice core, in which the entire transition (120,000 to 60,000 yr BP?) from the last and really warm interglacial (the Eem) to full glacial conditions is revealed by oxygen isotope ratio changes, would probably lead to the long-needed climatic counterpart to the continental ice volume records derived from analyses of foraminifera in deep-sea cores¹⁷⁻¹⁹.

These records show that at the end of the Eem some 120,000 yr ago the amount of continental ice began to increase, and that it grew from less than today to more than double the present amount within less than 10,000 yr. The drastic climatic deterioration, which triggered off the enormous glacier advance, may have taken place within a much shorter time interval²⁰, perhaps a century or less, to judge from a Greenland isotope record²¹ and from pollen records²²⁻²⁴. However, these records are poorly dated before 50,000 BP, and the possibility of a discontinuity in the layer sequences must be taken into account, the more so as the suggested duration (one millenium only) of the cold period that succeeded the Eem is inconsistent with the build-up of huge amounts of continental ice.

It is extremely important to study why and how abruptly the Eemian interglacial came to an end, because it might change our conception of atmospheric stability, and describe a possible mode of termination of the present interglacial. The new radioisotope ice dating technique will not be able to reveal the duration of the past climatic shift, but a counting of annual layers, deposited in a continuous sequence throughout the shift, may be feasible by modified detection techniques, because such layers, each 1 mm thick, probably exist some 80 m above the bottom of the ice sheet in central Greenland¹⁶. □

The origin of cosmic gamma-ray bursts — new Soviet results

From B. J. Teegarden

SINCE their accidental discovery in 1973 by Vela spacecraft, gamma-ray bursts have continued to be a mysterious and intriguing phenomenon. Lasting from a few seconds to a few tens of seconds, these bright flashes of gamma radiation occur randomly every one to two weeks. With one possible exception the identification of the sources of these events remains unsolved.

A multi-spacecraft network including experiments designed in the United States, France and the Soviet Union has been used to time the arrival of the gamma-ray burst wavefront to determine the arrival direction of the radiation. The only burst for which a source identification was made is the very unusual event of 5 March 1979 which displayed a very sharp, intense radiation spike lasting only 0.1 second and was followed by 8 second oscillations lasting for approximately 100 seconds. The arrival direction of this burst coincided with the remnant of a supernova explosion (labelled N49) in the Large Magellanic Cloud, our nearest neighbouring galaxy. This, however, was a highly unusual event, and its identification is still not universally accepted. At this time no other gamma-ray burst source identifications have been made. This is in spite of the fact that arrival directions for a number of events have been precisely determined.

A number of different models have been put forth to explain the energy source of these bursts. Two of these may be briefly summarized: the first hypothesizes that a solid body falls onto the surface of a neutron star providing a nearly instantaneous release of energy. The second proposes that infalling material from either a companion star or the interstellar medium gradually builds up a surface layer at the poles of a neutron star. Sufficient accumulation of material over a period of time leads to an unstable condition wherein a thermonuclear explosion can occur. In either case the resultant heating of the atmosphere immediately above the surface of the neutron star is sufficient to cause the release of an intense burst of gamma radiation.

Some dramatic new observations of gamma-ray bursts have recently been reported by E. P. Mazets and his colleagues at the Ioffe Physical-Technical Institute in Leningrad (see this issue of *Nature*, p.378) that shed important new light on the question of the origin of these events. Mazets and his co-workers have measured

the spectra of a large number of bursts using detectors on board the Soviet Venera 11 and 12 spacecraft. They have found remarkable emission and absorption features in 26 of the 80-90 events that were measured. Most of the spectra display pronounced absorption in the 30-70 keV range. This has been interpreted as being due to a phenomenon known as cyclotron absorption.

It is expected that extremely strong magnetic fields will surround a neutron star. This follows if the magnetic flux is conserved during the collapse of the parent star down to the neutron star. A simple extrapolation from the parent star to its compact offspring yields a magnetic field in the 10^{12} gauss range, a value far beyond any achieved in the laboratory. An electron in such a field will be constrained to spiral tightly about the magnetic field line. Quantum theory predicts that the electrons will be confined to discrete energy levels and that the transitions between these levels will be accompanied by either the emission or absorption of radiation. In a 5×10^{12} gauss magnetic field the characteristic energy of the transition is ~ 50 keV. The absorption and emission features in gamma-ray burst spectra observed by Mazets and his colleagues are therefore consistent with cyclotron processes in the strong magnetic fields expected to exist near the surface of a neutron star.

In addition to the 'cyclotron' emission and absorption features, Mazets and co-workers, as well as a group at Goddard Space Flight Center in the US, have seen in a smaller group of events (about 6) a broad emission line in the 400-450 keV range. When a positron and electron encounter each other and annihilate, they give off a characteristic emission at 511 keV known as annihilation radiation. Any such radiation originating near the surface of a neutron star will lose energy as it escapes from this intense gravitational field. This energy change is known as a 'gravitational redshift'. Present models predict that the magnitude of this shift will be 15-20% for a neutron star whose mass is the same as the Sun. Any 511 keV annihilation radiation produced near a neutron star surface would, therefore, emerge from the star's gravitational field with an energy in the 400-450 keV range.

It should be emphasized that these results are very recent and that the interpretations discussed here are not necessarily unique. These Soviet results, however, seem to point very strongly towards a neutron star origin for cosmic gamma-ray bursts. □

Plasmids and bacterial pathogens

from J.R. Saunders

THE way in which plasmids confer pathogenicity characteristics on host bacteria is of considerable concern in both developed and developing countries, and provided the central theme at a recent conference* in the Dominican Republic. Various aspects of plasmid biology were covered, ranging from the mechanisms of genetic transposition and plasmid replication to the epidemiology of antibiotic-resistant bacteria in human and animal populations.

Plasmids probably determine only a small proportion of all bacterial virulence traits. However, they may provide sufficient additional genetic information to convert relatively innocuous organisms into pathogens. This is particularly true of enteropathogenic strains of *Escherichia coli*, the prime cause of travellers' diarrhoea and other economically important diseases of humans and domesticated animals. The distressing symptoms of these conditions are largely produced by one or more plasmid-specified enterotoxins, which include a single type of heat-labile toxin (LT) and probably at least two distinct heat-stable toxins (ST). S. Falkow (Stanford) reported a striking similarity between the gene for LT and that for the cholera toxin, despite the fact that the former is always plasmid-borne in *E. coli* and the latter chromosomally determined in *Vibrio cholerae*. The difference in disease patterns, apparently specified by the same virulence determinant, may reflect the different methods by which the two causative agents actually deliver the toxin to their human hosts. This emphasizes how heavily the expression of pathogenicity determinants depends on the genetic and physiological infrastructure into which they become inserted. It is interesting in this context that certain characteristics, such as particular chromosomally determined somatic (O) antigen types, are found habitually among enterotoxigenic strains of *E. coli*.

Haemolytic strains of *E. coli* can frequently be isolated from infected body fluids. However, the exact role of haemolysins in the pathogenicity of these bacteria is not clear. In *E. coli*, α -haemolysins are determined either by the chromosome or by Hly plasmids. Such plasmids isolated from different strains have been shown by W. Goebel (Wurzburg) to share a common haemolysin determinant. This consists of three cistrons, *cisB* (1,500 base pairs) determining a protein located in the outer membrane and probably responsible for the transport of haemolysin, *cisA* (2,500 base pairs) encoding a precursor of α -haemolysin, and *cisC* (about 500 base pairs) which is apparently required for the

conversion of the *cisA* product to active α -haemolysin. Despite the wide distribution of the Hly determinant it does not seem to constitute part of a transposon (see De La Cruz *et al.* *J. Bact.* **143**, 825; 1980). This contrasts with one of the ST genes which is known to be transposable (So *et al.* *Nature* **277**, 453; 1979).

The ability of enteric bacteria to adhere to the gut wall is a primary requirement for their pathogenicity. The best studied of such plasmid-mediated determinants are those for the filamentous surface protein antigens K88 and K99, which enable enteropathogenic *E. coli* to adhere to the mucosa of the small intestine of pigs and calves respectively. Similar pilus-like structures, termed colonization factors (CFAI and II), are plasmid-encoded in human enteropathogenic *E. coli*. Two groups (J. van Embden, Balthoven and G. Dougan, Dublin) reported the cloning and genetic analysis of the K88 and K99 antigens. Dougan has found that at least four genes, organized into two operons, are involved in the expression of the K88 antigen in *E. coli* minicells. Operon I comprises three genes transcribed from *adhA* (encoding a protein of molecular weight 70,000 which may be the basal structure for membrane attachment of the antigen) through *adhB* (29,000-MW protein) to *adhC* (17,000-MW protein). *adhC* may encode a positive regulator for operon II containing a single gene *adhD* determining the 23,000-MW subunit of the K88 antigen itself.

In addition to adhering to the intestine, some enteric pathogens are able to invade the gut tissues. D. Kopecko (Washington) described plasmids of about 120 megadaltons in *Shigella sonnei*. Loss of these plasmids results in transition of host strains from the virulent, smooth colonial form I to a virulent, rough colonial form II. Such plasmids apparently determine the synthesis of the form I somatic (O) antigen required for invasion of colonic epithelium.

The potential of bacteria as invasive pathogens is obviously enhanced by their ability to withstand the antibacterial properties of serum. A number of unrelated antibiotic-resistance plasmids and temperate bacteriophages, such as λ , confer on host bacteria resistance to complement (activated by either classical or alternative pathways). K. Timmis (Berlin) showed that serum resistance conferred by the conjugative plasmid R6-5 is determined by the product of the *traT* gene. This is a 25,000-MW protein responsible for the surface exclusion (prevention of conjugative mating with related donors) and present as 20,000 copies in the outer membrane of *E. coli* carrying R6-5. M. Binns (St Louis) has demonstrated that the *traT* product of another conjugative

plasmid, R100, impairs the formation of the terminal complement complex. Furthermore, *traT*-containing cells remain resistant to complement even if they have been pretreated with antibodies to *traT*. This suggests that the *traT* protein does not actively protect bacteria against serum but has a passive effect, possibly involving subtle alteration of the architecture of the cell envelope. In addition, studies by Timmis of mutants in the *traT* gene indicate that the serum-resistance and surface-exclusion properties of *traT* protein may be distinct. Whatever the mechanisms involved, serum-resistance determinants, such as *traT*, may provide a selective advantage leading to the maintenance of conjugative resistance plasmids in pathogenic bacteria.

An important prerequisite for invasive pathogens is the ability to proliferate in the low free-iron conditions prevailing in animal tissues. A significant proportion of *E. coli* strains causing bacteraemia in humans or animals are found to carry ColV plasmids. In addition to encoding colicin V production and serum resistance, such plasmids specify accessory iron-sequestering mechanisms. P. Williams (Leicester) has shown that they determine an extracellular iron-chelating compound of low molecular weight which competes successfully with transferrin for iron *in vivo*. In addition, they specify, together with chromosomally determined components, an active iron uptake system. The possession of these extra mechanisms for acquiring free iron is thus sufficient to allow growth of *E. coli* in the tissues of infected animals.

Knowledge gained from *E. coli* should facilitate the analysis of more complex, chromosomally determined pathogenic mechanisms in less tractable organisms. And cloning of virulence determinants provides the promise of effective vaccines against enteric and other infections. □

100 years ago

PHYSICAL NOTES

M. Plantamour continues to study with his sensitive levels the phenomena of periodic rise and fall of the ground which he has observed in Switzerland. He believes he has established a connection between these periods and those of the changes of temperature of the earth's surface, there being an annual change of level in an east-west direction corresponding with the mean temperatures of the surface during the year.

From *Nature* **23**, 31 March, 517, 1881.

Superluminal radio sources

from Guy Pooley

THERE was some understandable disbelief when it was reported about 10 years ago that some radio sources appeared to expand at velocities greater than that of light. Astronomers, though, are used to the impossible and since then there have been advances in both theory and observations. The article by Pearson *et al.* of the Cal Tech radio astronomy group (see this issue of *Nature*, p.365) describes observations of one particular quasar, 3C273, made with the US very long baseline interferometry (VLBI) network. They have applied the techniques of map-making developed by Readhead and Wilkinson at Cal Tech using so-called 'closure phase' measurements.

These observations all require the highest possible angular resolution — 1 milli-arcsecond or better — that at present can only be achieved by radio astronomers using transcontinental or inter-continental baselines. With these systems, it is not yet possible to measure absolute phase differences between signals arriving at the different stations; uncertainties in the clocks, geometry of the Earth, atmospheric paths and so on are too large. But if more than two receiving stations are available, there is some redundancy in the phase information, and the more stations in use the greater are the constraints that this places on the data. Pearson *et al.* used four, sometimes five stations and therefore six or ten baselines. Earlier long-baseline observers had to be content with fringe amplitude information only, and this was used to constrain models for the distribution of the radio sources on the sky; but it could not, for example, be used to distinguish between models which differed by a rotation of 180°.

The high apparent transverse velocities have been detected in several radio sources: quasars like 3C273, 3C279 and 3C345, and a galaxy, 3C120. These sources have been studied by VLBI techniques, until now without the use of closure phase. The results were perhaps most convincing in the case of 3C345, which could be modelled well by a simple double source and showed $v_{\text{apparent}} \approx 7c$.

3C273 is a source of some complexity. On the large scale, it has coincident radio and optical 'jets' some 20 seconds of arc (80 kiloparsecs) long. This jet is of course not detected in the long-baseline study, which shows the expanding feature some 0.01 seconds from the (presumed) central object. This feature is apparently moving with a transverse velocity of about 10c, rather more than had been estimated from the phaseless observations. The orientations of the large- and small-scale structures differ by about 20°.

One thing that cannot be done with closure phase is to find the absolute position of the source. It is therefore not yet possible to say with certainty which

features in the maps are 'stationary'.

The theoretical problems are not entirely new; Nova Persei (1901) gave similar difficulties, which were explained in terms of simultaneous excitation of separated clouds by a shock-front. Blandford, McKee and Rees reviewed the possibilities for the expansion of extragalactic radio sources (*Nature* 267, 211; 1977). The range of possibilities is large. There are the 'acausal' models such as the 'Christmas tree' version involving independent sources whose unrelated eruptions mimic expansion and there are models depending on the variation of propagation conditions either close to the source or in the intervening space (gravitational lenses, or scintillation in some intervening medium of galaxy). Neither of these general types seems to explain naturally the common features, particularly the fact that the sources always seem to expand.

The most popular models involve ejection of matter in some form of relativistic jet; there are several variants in which this can lead to high apparent transverse velocities. One particular attraction lies in the fact that the brightness temperatures of some compact radio sources, as implied by their rapid variations and inferred small sizes, are already uncomfortably high for the incoherent synchrotron process; a relativistic expansion eases this problem.

Scheuer and Readhead (*Nature* 277, 182; 1979) have developed one attractive version of this model. In it, they postulate that radio emitting objects are emitted repeatedly along one axis from the central object. Most of the light comes from the central, stationary object. The relativistic γ for the approaching component must range up to around 10, and any receding components would be practically undetectable. In their model, it is those quasars or galaxies whose axes are aligned almost along the line of sight for which dramatic effects are observed; those which are not so aligned are radio quiet, or at least radio dim, and may form central components of 'classical' double sources.

Pearson *et al.* make the point that the Scheuer-Readhead model is in some danger because of the dearth of radio-quiet quasars of comparable magnitude to that of 3C273; this is one of the questions for which careful statistics need assembling, and this can be done only by systematic mapping of expanding sources of this type. Further questions can now be asked; is the expansion uniform? When the size doubles, it might be surprising if the speed does remain constant. What are the statistics of a complete sample of quasars? Are the detailed structures consistent with the expanding jet models? The evidence is that rapid expansion is a very common feature among compact radio sources. □

DNA methylation and control of gene expression

from Tomas Lindahl

ABOUT 3% of cytosine residues in mammalian DNA are present as 5-methylcytosine, methylation of cytosine usually occurring soon after DNA synthesis. The existence of such signal groups has often stimulated speculation, but hard facts on their role have been scarce. However, recent experiments suggest a role for DNA methylation in regulating or blocking transcription of DNA. Such data further indicate that specific demethylation events may be necessary for gene expression during development and differentiation. A meeting on the subject was recently held at the University of Cologne* and one point that emerged was that an understanding of the role of DNA methylation in mammalian cells is unlikely to be obtained from studies on lower organisms and other model systems.

The relationship between DNA methylation and ribosomal gene function in several different organisms was reviewed

by A. Bird (MRC Mammalian Genome Unit, Edinburgh). Mouse cells carry about 100 ribosomal RNA genes per cell, occurring in two forms, unmethylated and heavily methylated. In various inbred mouse strains, between 5 and 30% of the sequences are methylated. Only the unmethylated ribosomal genes in mouse liver appear to be expressed, and the data point to an inverse correlation between DNA methylation and transcription. However, in *Xenopus laevis* all the chromosomal ribosomal DNA is heavily methylated, and this vertebrate clearly transcribes methylated sequences, although transcription may depend on the presence of an undermethylated region within the non-transcribed spacer between the ribosomal DNA genes. In contrast, *Drosophila* cells contain virtually undetectable amounts of 5-methylcytosine, so this organism is not likely to utilize DNA methylation for control of gene activity.

Many plant cells contain exceptionally high concentrations (up to 25%) of 5-methylcytosine in their DNA, and transcription of such methylated DNA does take

*A meeting on 'DNA Methylation and Genome Organization' (4-7 March, 1981) was organized by the Institute of Genetics, University of Cologne.

place (B. Deumling, Heidelberg). The reason for the heavy DNA methylation in plants remains unknown, but replacement of cytosine with a more radiation-resistant derivative could provide the cells with an increased tolerance to sunlight.

In animal cells, methylated cytosines are often present in relatively large amounts in non-transcribed satellite sequences, and fluctuation of the number of such regions in different cell types has often obscured more interesting variations in DNA methylation. This problem has been circumvented by examining the methylation of specific DNA sites within individual genes using restriction enzyme analysis and cloned DNA fragments as probes. Some of the most interesting recent data have come from work with DNA tumour viruses. L. Vardimon and W. Doerfler (Institute of Genetics, University of Cologne) showed for three different adenovirus type 2 transformed hamster cell lines, which contained the entire gene for the virus-coded 72K DNA binding protein, that the mRNA for the protein (as well as the protein itself) was present in only one of the cell lines. In the latter, the integrated viral DNA was unmethylated, as judged by its sensitivity to the *HpaII* restriction endonuclease, while the corresponding DNA sites in the two other cell lines were methylated. Similar results were obtained with a cloned viral DNA fragment methylated *in vitro* at a few cytosine residues. Furthermore, *in vitro* transcription studies (performed together with J. Corden, Strasbourg) indicated that the initiation of transcription of the gene for the 72K protein was severely inhibited by methylation of the DNA.

An oncogenic herpesvirus, Herpes saimiri, is similar to the adenoviruses in that the DNA in virus particles is completely unmethylated, while the largely non-expressed viral DNA present in virus-induced tumours or in transformed cell lines is heavily methylated (B. Fleckenstein and C. Kaschka-Dierich, Erlangen and R.C. Desrosiers, New England and Primate Research Center). As with the similar human lymphotropic herpesvirus, Epstein-Barr virus, the viral DNA in H.saimiri transformed cells is largely carried as multiple copies of nonintegrated plasmid DNA; S-adenosylhomocysteine treatment (which inhibits DNA methylation) markedly decreased the amount of viral DNA carried per cell.

As might be expected, there are exceptions to the rules. SV40 DNA from virions is apparently completely unmethylated. Microinjection experiments with SV40 DNA methylated *in vitro* with a highly purified rat liver methylase (which acted on all CpG sequences as well as several other C residues so that 2.5% of the cytosines were converted to 5-methylcytosine) seemed at variance with some of the data obtained for other tumour viruses (D. Simon and A. Graessmann, Berlin). On microinjection of 2 to 4 viral DNA molecules per host cell, there was apparently no

active demethylation of the SV40 DNA, but nevertheless, the methylated DNA induced SV40 determined antigens as effectively as nonmethylated DNA. Similar data were obtained with both permissive and nonpermissive host cells, so these experiments appear to suggest a difference in the sensitivity to DNA methylation between SV40 and larger DNA tumour viruses. The problems with this approach are that the incoming methylated DNA may have been replicated into nonmethylated daughter molecules, or the methylated DNA preparation may have contained a minority of unmethylated molecules which were transcribed.

An elegant system for the investigation of the effect of DNA methylation is provided by studying transformation of thymidine kinase deficient cells using cloned thymidine kinase genes. M. Wigler (Cold Spring Harbor Laboratory) used genes from Herpes simplex type I and from chicken, and compared the biological activity of unmethylated DNA and DNA methylated *in vitro* with *HpaII* methylase. The methylated genes showed distinctly lower transformation efficiency than the unmethylated controls, although the two kinds of molecules had the same frequency of incorporation. Methylation either in the promoter region or in the structural gene caused equal inhibition compared to unmethylated controls, so specific methylation of the promoter region did not seem to be of unique importance.

In the above experiments, the methylated cytosine residues of the incoming DNA, which were present in CpG sequences, appeared to serve as their own genetic determinants and were largely preserved for many generations. It seems clear that mammalian cells contain a maintenance methylase to retain the general methylation pattern of DNA. Similar data were presented by H. Cedar (Hebrew University, Jerusalem), who replaced dCTP with 5-methyl-dCTP in *in vitro* replication to obtain a very highly methylated DNA molecule. So far, only model experiments had been performed with the replicative form of Φ X174 DNA, containing one strand with all cytosines replaced by 5-methylcytosine. After introduction into hamster cells, where the DNA integrated at low efficiency, methylated sites at all CpG sequences seemed to be preserved while other 5-methylcytosines were replaced by unmodified cytosine on replication. This indicates that the maintenance methylase requires the CpG sequences for activity. However, the slow progress made in the characterization of mammalian DNA methylase(s) makes such observations seem somewhat preliminary.

Detailed restriction enzyme analysis of methylation sites within the human globin gene clusters (R.A. Flavell, National Institute for Medical Research, London) shows that many methylated residues persist also in genes that are being expressed, but globin DNA that is transcribed is

undermethylated compared to that present in sperm. These observations again seem in accord with the general idea that DNA methylation may play a role in controlling and preventing transcription. One way of overcoming inherent problems that arise from using DNA cloned in *Escherichia coli* in biological assays such as *in vitro* transcription is to use DNA heavily methylated *in vitro*, on the assumption that it is easier for a cell to specifically demethylate DNA than to methylate it, in analogy with the demethylation that apparently occurs with germ-line globin DNA on activation. It is not known how this demethylation is achieved, although several models are possible. For example, DNA may be replicated in a cellular compartment in which methylation at some sites does not occur, or specific DNA binding proteins may prevent the methylation at certain loci during replication. Alternatively, some 5-methylcytosine could be actively replaced by unmodified cytosine in the same way as misincorporated uracil residues are efficiently removed from DNA.

The role of DNA methylation in simpler organisms than mammalian cells is also being studied. In an important advance, R. Sager (Sidney Farber Cancer Institute, Boston) has shown that the maternal inheritance of chloroplast genes in *Chlamydomonas* results from the methylation of chloroplast DNA in female (but not in male) gametes, leading to the preferential degradation of the chloroplast DNA of male origin in zygotes. In cells carrying a *mat-1* mutation, the male chloroplast DNA also becomes methylated, and consequently the inheritance pattern is converted from maternal to biparental. M. Meselson (Harvard University) discussed the role of DNA adenine methylation for the direction of mismatch repair of phage λ heteroduplex molecules. Some, but not all, of various constructed mismatches having one strand methylated *in vitro* with a DNA methylase and the other strand unmethylated were susceptible to repair. While DNA sequence data on the regions around the mismatched residues are not yet available, it seems clear that the mismatches that are being repaired have to be present in a heteroduplex structure in which only one strand of the DNA is methylated, and that repair then occurs selectively in the unmethylated strand. Thus, neither fully methylated DNA nor unmethylated DNA is susceptible to mismatch repair, and it presumably only takes place in newly replicated DNA with the parental strand methylated. While mammalian cells probably also have the ability to perform mismatch repair, they do not seem to contain 6-methyladenine in their DNA, so it is an open question whether DNA methylation can guide mismatch repair events in higher organisms. □

Tomas Lindahl is Professor of Medical Biochemistry at the University of Gothenburg, Sweden, presently at the Imperial Cancer Research Fund Laboratories, London.

ARTICLES

Superluminal expansion of quasar 3C273

T. J. Pearson, S. C. Unwin, M. H. Cohen, R. P. Linfield, A. C. S. Readhead, G. A. Seielstad, R. S. Simon & R. C. Walker*

Owens Valley Radio Observatory, California Institute of Technology, Pasadena, California 91125, USA

Maps of the radio structure of 3C273 show directly that it expanded with an apparent velocity 10 times the speed of light from mid-1977 to at least mid-1980.

THE radioastronomical technique of very long baseline interferometry (VLBI) achieves an angular resolution better than 1 mas, equivalent to a physical resolution of the order of light-years in even the most distant galaxies and quasars. At this resolution, changes in the structures of such objects can be easily detected. In four extreme cases, three quasars (3C273, 3C279 and 3C345) and one galaxy (3C120) have been seen to expand with an apparent speed more than twice the speed of light, c (ref. 1). The evidence for such 'superluminal' expansion has been based on rather limited data, and the interpretation has been uncertain; but the recent development of the VLBI technique of hybrid mapping² allows us to map the radio brightness distribution to show the expansion directly and unambiguously.

Table 1 Observations

Epoch	Antennas*	Frequency† (MHz)	Flux density‡ (Jy)
1977.56	KGFO	10,651	40.9
1978.24	KGFO	10,651	44.5
1978.92	KGFO	10,651	34.9
1979.44	BKGFO	10,651	30.7
1980.27	BKG O	10,651	27.0

† The centre frequency of the 2-MHz band.

‡ Measured during the observation; typical uncertainty 0.5 Jy.

The 10.65-GHz observations were made in left-circularly polarized radiation, and the 5.0-GHz observations were made in linearly polarized radiation with the E-vector in PA 90°.

This article presents maps of the quasar 3C273 which show that it was expanding with an apparent velocity $v = (9.6 \pm 0.8)c$ between 1977.5 and 1980.5. (We assume $H_0 = 55 \text{ km s}^{-1} \text{ Mpc}^{-1}$ and $q_0 = 0.05$ throughout.)

3C273 is a 13-mag quasar with a redshift of 0.158 (ref. 3). An optical jet extends from a distance of ~ 10 arcs to ~ 25 arcs from the quasar in position angle (PA) -137° (ref. 4). The projected length of the jet is 84 kpc. The radio emission comes principally from two locations: a compact component (3C273B) coincident with the quasar, and a more diffuse component

(3C273A) near the end of the jet⁵⁻⁷. The compact component 3C273B consists of a flat-spectrum core with a steeper-spectrum extension in PA -117° (ref. 8). This direction is approximately that of the superluminal expansion. As the angular scale is increased, the predominant position angle rotates until it is more closely aligned with the optical jet⁹. Recent observations of 3C273 in all wavebands have been reviewed by Ulrich¹⁰.

3C273B was one of the first sources to be studied with VLBI^{11,12} and has been the subject of many subsequent observations. Changes in the visibility function were first observed in 1971^{13,14}. Although these observations were confined to a single baseline, it was immediately clear that the changes could be explained by a simple expansion. The data permitted other explanations, however, including models in which the centres of emission remained fixed while varying in intensity¹⁵. With more complete visibility data¹⁶⁻¹⁸, it became clear that the structure was more complex than a simple linear model of two or three components, and that the overall extent of the brightness distribution continued to increase. To avoid some of the ambiguities inherent in model-fitting, Cohen *et al.*¹ examined the visibility function measured between 1970 and 1977, and found that the first minimum (that at shortest projected baseline) in the visibility amplitude moved steadily towards smaller baselines, indicating a steady increase in the size of the source. They took as a measure of the angular size the quantity θ^* , defined as $1/(2w)$, where w is the projected baseline (in wavelengths) at the first minimum. If the source were a simple double, θ^* would be the separation of the two components. A later analysis¹⁹ of all the data available up to 1977.41 showed that the time-dependence of θ^* approximated a straight line with a slope of $0.41 \pm 0.04 \text{ m arc s yr}^{-1}$, corresponding to an apparent linear expansion rate of $v/c = 5.2 \pm 0.5$. This steady increase in θ^* (Fig. 16 of ref. 19) has provided the strongest evidence for superluminal expansion in 3C273. We know that 3C273 was not accurately represented by a simple double model during the period spanned by these observations, so θ^* was not a true measure of its angular size. We should not be surprised therefore that the maps presented here show that the true expansion speed differs from that inferred from the measurements of θ^* .

Maps

Since 1977 we have been monitoring 3C273 at two frequencies, 10.65 GHz and 5.0 GHz, using four or five antennas. The new observations are better than the old for several reasons: (1) we have used more antennas, sampling the visibility function at more spatial frequencies; (2) we have when possible included an antenna in Europe in addition to American antennas, thereby improving the resolution; (3) we have measured closure phase²⁰ in addition to visibility amplitude. These improvements enable us to make hybrid maps of the brightness distribution². The increase in the quantity of data has eliminated the ambiguities of model-fitting. The first maps at these two frequencies have already been published^{8,21}, and we have now observed a total of six epochs at 10.65 GHz and four epochs at 5.0 GHz (Table 1).

* Present address: National Radio Astronomy Observatory, Edgemont Road, Charlottesville, Virginia 22901, USA.

Fig. 1 Maps of 3C273B at 10.65 GHz at five epochs (see Table 1). The same restoring beam (an elliptical gaussian with FWHM 4.2×1.2 marc s, with the major axis in PA -15° , indicated by the hatched ellipse) is used for all the maps. The dynamic range of the maps is about 20:1. The contour levels for all the maps are 1.2, 2.4, 3.6, 5, 7, 9, 12, 15, 20, 25, 30 and 35×10^9 K. The absolute position of the source cannot be accurately determined from the data; here the maps have been lined up on the sharp eastern edge to show the motion of the weaker western component. The map for epoch 1977.56 is from ref. 8, which gives more details of the map-making procedure.

Full details of these observations will be published elsewhere; here we describe only the 10.65-GHz maps and the superluminal expansion that they reveal.

Figure 1 shows maps made from five of the six 10.65-GHz observations. It was not possible to make a reliable map from the observation of 1980.27 owing to a failure at one of the antennas. The beam (hatched ellipse in Fig. 1) is very elongated because 3C273 is close to the celestial equator, where the presently available network of antennas has very poor north-south resolution. Fortunately the principal extension of the source is close to the direction of maximum resolution. Two of the experiments included an antenna in Europe as well as those in America (see Table 1). For these, the east-west resolution was improved by a factor of two. To make the maps directly comparable, however, the restoring beam appropriate to the lowest-resolution observations was used for all the maps.

The five maps in Fig. 1 span a period of 3 yr. All the maps show a bright eastern peak and a lower-brightness extension to the west. In all cases there is a local maximum in the western

Fig. 2 Brightness-temperature profiles through the maps of Fig. 1 along the principal axis of the source (PA -116°). The profiles have been truncated to show the evolution of the weak western component, and they have been aligned at the half-power point on the eastern edge, labelled 0 on the abscissa. The vertical displacement between the profiles is proportional to the difference in epoch. The profile of the restoring beam (FWHM 1.42 marc s) is indicated.

extension between 6 and 8 marc s from the main peak. The most striking difference between the maps is the steady increase in the separation of this local maximum from the main peak. The position angle defined by the main peak and the secondary maximum has not changed significantly; in all the maps it is $-116^\circ \pm 2^\circ$. The maps also show that the source is not straight but curves to the south with increasing separation from the main peak. This phenomenon has been noted previously^{8,9,18}.

Expansion velocity

The profiles in Fig. 2 show that the separation of the western maximum from the main peak increased from ~ 6 marc s to ~ 8 marc s between 1977.5 and 1980.5. The time-dependence of the separation, θ , is shown in Fig. 3. In addition to the 10.65-GHz points, one 5-GHz measurement is included to show that the size of the source is the same at both frequencies. (The other 5-GHz observations do not have sufficient resolution to be directly comparable, but they are consistent with this conclusion.) θ was determined by measuring the separation of the peak of the western maximum from the half-power point in the sharp eastern edge, and then subtracting half the FWHM of the restoring beam (0.71 marc s) to correct for resolution. This measure is less affected by changes in the internal structure of the eastern component than a separation measured to the peak

of the eastern component. In all cases the measurement was made along a line with PA -116° .

The values of θ all fall remarkably close to a straight line in Fig. 3, indicating that the expansion is linear, with no evidence for acceleration or deceleration. The angular expansion rate, derived by a least-squares fit of a straight line (omitting the 5.0-GHz point), is 0.76 ± 0.04 marc s yr^{-1} , corresponding to a linear expansion rate of $v/c = 9.6 \pm 0.5$. The extrapolated intercept $\theta = 0$ is at 1970.1 ± 0.6 . If the expansion speed has not changed, one might expect to see an increase in total flux density at this epoch, corresponding to the formation of the new component. No such increase was seen²². The flux density of 3C273 has irregular variations with a time scale of one or two years, but it is not possible to correlate changes in the flux density with structural changes.

θ is larger than the values of θ^* extrapolated from the older data, but this is due to the difference in measuring technique. θ^* , being determined directly from the visibility function, is not related in a simple way to the brightness distribution except when the source is a simple double. If the expansion were conformal (if the brightness distribution retained the same shape but simply increased in scale), θ would differ from θ^* by a constant factor, but the real behaviour is more complicated.

Acceleration?

The angular size of 3C273B derived by extrapolating the expansion rate shown in Fig. 3 back to the early 1970s is smaller than the size then observed. This implies that either the expansion speed has increased, or the expansion has not been conformal. It is possible to devise non-conformal models that can explain the qualitative features of the observations without requiring an acceleration. In triple models, unlike doubles, the positions of the minima depend not only on the separations of the components but also on their relative intensities. One such model involves one fixed component and two components both moving with the same velocity. Suppose that at the earlier epochs (1970–75) the source consisted of three principal compact components: a core C at the eastern end, with flux density S_C , and two components A and B moving away from the core at $10c$ in PA -116° , with flux densities S_A and S_B . Let A be the more distant component. When the separation of A from C is much greater than the separation of B from C, the first visibility minimum measures the distance between A and the centroid of B and C. The expansion rate derived from θ^* is then $10cS_C/(S_B + S_C)$. This rate was $5.6c$ (ref. 19), implying that $S_B \approx S_C$ in 1970–75. Component A has since decayed below the level of detectability, and the new maps measure the separation of B from C which is increasing at $10c$. Of course, this model is an oversimplification, as the maps show additional components lying between B and C.

It is not possible to eliminate models involving acceleration, but a constant-velocity model seems to be favoured by the constancy of the expansion rate shown by the maps of Fig. 1. If the constant-velocity model is correct, we would expect further components to appear in maps made during the next few years.

Relativistic jet

Although several explanations have been suggested for superluminal expansion^{23,24} we shall discuss only the model²⁵ in which the expansion is presumed to represent a physical motion almost directly towards the observer; we are looking down a jet of relativistic material expelled from the quasar. The eastern end of 3C273B is the 'core', the point at which the jet becomes optically thick. In a steady flow, this point remains fixed even though the radiating material has a high velocity. The moving (western) component is a 'knot' propagating outwards along the jet. At large distances, the jet becomes visible as the optical jet, and the region of impact on the external medium is represented by the radio source 3C273A. This model accounts for (1) the milli-arcsecond morphology of 3C273B; (2) the fact that the expansion is roughly along the source axis; and (3) the approximate alignment between the axis of 3C273B and the optical jet.

Fig. 3 Angular size of 3C273 as a function of time, measured as described in the text. Five 10.65-GHz measurements (●) and one 5.0-GHz measurement from 1979.92 (○) are shown. The dashed line at the bottom is an extrapolation of the expansion rate derived from observations of θ^* before 1977 (ref. 19). The solid line is a least-squares fit to the 10.65-GHz measurements, and has a slope of 0.76 marc s yr^{-1} .

(The difference of 20° between the radio axis and the optical axis is attributed to curvature in the jet⁹.) If the constant-velocity interpretation of the older data is correct, then at least two knots have been ejected from the core in a period of ~ 10 yr. Alternatively, an accelerating expansion can be accommodated in this model: it could be due to real acceleration in the flow along the jet or to a curvature of the jet.

To account for an apparent transverse velocity v as large as $9.6c$, the angle ϕ between the jet and the line of sight must be small. The apparent velocity v is related to ϕ and to v_0 , the space velocity of the moving feature, by

$$v = v_0 \sin \phi / \{1 - (v_0/c) \cos \phi\}$$

(ref. 26). If $v = 9.6c$, this equation requires that $\phi < 11.9^\circ$ ($\cos \phi > (v^2 - c^2)/(v^2 + c^2)$) if $v_0 < c$, and v_0 is minimized when $\phi = 6.0^\circ$. The probability that ϕ should be as small as 11.9° in a randomly selected quasar is 1%, or 2% if the jet is two-sided.

3C273 is far from being a randomly chosen quasar: it is the closest quasar in the 3CR sample²⁷ and has an intrinsic optical intensity ~ 4 times the intensity of the other quasars in the sample. It is surprising that it should also be exceptional in having a jet pointing almost directly at Earth. A possible explanation is that the optical radiation, like the radio, is not isotropic. There is no direct evidence for this, but beaming of the optical continuum cannot be ruled out. If the optical radiation is isotropic, then the small angle between the radio jet and the line of sight causes grave difficulties for the simple relativistic theories. For example, Scheuer and Readhead²⁸ attribute the difference in radio intensity between optically selected and radio-selected quasars to the relativistic beaming of the radio radiation—radio-selected quasars point towards Earth. We would expect on this model to see 50–100 radio-quiet quasars of comparable optical magnitude to 3C273, which we do not. It may be necessary to consider other models in which the radio radiation is not confined to so small an angle; one such model has been suggested by Rees²⁹.

Conclusion

The maps presented in Fig. 1 provide the first direct and unambiguous evidence of superluminal expansion in any radio source. For the period of 3 yr spanned by the observations the superluminal expansion could be attributed to the movement of

a single knot away from the nucleus along the jet. The apparent constant velocity of 9.6c observed in this period is an important constraint on theories of apparent superluminal expansion. Further observations of both 3C273 and other superluminal sources are needed to show whether the expansion is always at a constant velocity; the present results show that such analyses must be based on maps, rather than on the motion of features in the visibility function.

The observations described here were made under the auspices of the United States VLBI Network Users Group. We

Human immunoglobulin κ light-chain genes are deleted or rearranged in λ -producing B cells

Philip A. Hieter*, Stanley J. Korsmeyer†, Thomas A. Waldmann† & Philip Leder*

* Laboratory of Molecular Genetics, National Institute of Child Health and Human Development,
† Metabolism Branch, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205, USA

We have examined 10 human λ light-chain-producing B lymphocytes and found that genes for the κ constant region have been deleted in each. Only one of the 20 possible κ alleles in these cells has been retained and even this exception is rearranged. In contrast, λ constant region genes remain in the germ-line configuration in each of the eight κ light-chain-producing human B lymphocytes examined. Such observations suggest a hierarchy of light-chain-gene rearrangement beginning with κ and proceeding to λ .

A NUMBER of choices are involved in the differentiation of an antibody-producing lymphocyte. For example, usually only one light-chain gene is functionally expressed in a given cell, the choice having been made between the two light-chain classes (κ or λ) and their respective alleles¹. In addition, after commitment to the expression of a particular light-chain, the phenotypically excluded class and allele apparently remain silent throughout the functional life of the lymphocyte. These phenomena are called isotypic (κ versus λ) and allelic (one κ allele versus the other) exclusion. Whether they are tightly programmed or stochastic remains an extremely interesting but unanswered question.

Fortunately much of what we know about the formation of an active mouse κ gene is relevant to the question of allelic exclusion. In some B (antibody-producing) cells, the silent allele remains in the germ-line configuration and has not undergone the somatic V/J rearrangement necessary to form an active gene^{2–4}. In other cells, the silent allele has undergone V/J recombination but, because of the variability of this reaction, produces an out-of-phase J sequence and, consequently, a nonsense gene^{5,6}. In still other cells, recombination occurs at other than a J region making it impossible to form a coherent coding sequence^{7,8}. In each of these instances, the molecular basis for the silence of the excluded allele is clear, but the basis for the selection and control of this process, if any, remains obscure.

Little is known of the nature of isotypic exclusion, because studies of λ/κ expression in the mouse are necessarily limited by the fact that the λ class is expressed at low frequency in this organism. Recently, however, Alt *et al.*⁹ examined three long-

established λ chain-producing mouse myeloma lines and found that κ genes had been rearranged in two of them and possibly lost in a third. This observation led them to a proposal (see below) regarding the control of allelic and isotypic exclusion by the formation of functional genes. This proposal can be usefully pursued in man. In contrast to the mouse, human immunoglobulins are composed of one-third λ light-chain-bearing molecules and, therefore, the human λ gene system is likely to contribute significantly to antibody diversity. Accordingly, we have turned to man and an array of established B-cell lines and freshly obtained leukaemic cells to ask whether the structure and arrangement of these genes offer some clue as to the mechanism or order of their selection.

We show here that at least one light-chain gene in each light-chain-producing B cell has undergone rearrangement while its allelic partner has either remained in the germ-line configuration, undergone a second rearrangement or been lost. In each cell expressing a κ gene, the λ genes are present in their germ-line configuration, but in surprising contrast, in each λ -producing cell, κ genes have been either deleted or undergone a rearrangement. This consistent correlation suggests, among other possibilities, a putative hierarchy of light-chain-gene rearrangements in which the process is ordered so that it usually progresses from the κ to the λ genes.

κ genes are rearranged and deleted in κ -expressing cells

The arrangement of the κ light-chain genes in human κ -expressing B cells was determined using a radioactive DNA

autoradiograms were developed. The germ-line (embryonic) κ gene map demonstrating the 12-kilobase *Bam*HI C_{κ} -containing fragment and the 2.5-kilobase *Eco*RI embryonic C_{κ} -containing fragment (hatched bar) which was used as the C_{κ} probe are shown. The four human J_{κ} gene segments identified by heteroduplex analysis¹⁰ are indicated.

fragment containing the human κ constant region gene¹⁰ as a hybridization probe to detect this gene among fragments generated by *Bam*HI endonuclease digestion of genomic DNA (Fig. 1). Non-rearranged genomic DNA yields a single *Bam*HI fragment containing the single C_{κ} and four human J_{κ} segments¹⁰. Examination of such *Bam*HI fragments from non-B cells (placental tissue, fibroblasts or T cells) derived from 24 different individuals (see representative controls in Figs 1 and 4) showed them all to be in the germ-line configuration. Human κ light-chain-expressing B cells (including lymphocytes derived from three high-count chronic lymphocytic leukaemia patients, three B-cell lines established spontaneously from κ -expressing B-cell malignancies, and two κ -secreting Epstein-Barr virus-transformed human B-cell lines) were then examined. All eight κ -expressing B cells demonstrated at least one *Bam*HI fragment rearrangement when compared with the germ-line configura-

tion (Fig. 1). The second C_{κ} allele remained in the embryonic configuration in four cases, showed a DNA rearrangement in two cases and was deleted in two cases.

λ genes are rearranged in λ -expressing B cells

Analyses of human myeloma proteins¹¹ demonstrated that the λ constant region consists of at least four non-allelic forms in man which bear the non-allelic markers, Kern⁺Oz⁻, Kern⁻Oz⁺, Kern⁻Oz⁻ and Mcg. To identify these genes in λ chain-producing cells, we used a C_{λ} probe consisting of a mixture of two ³²P-labelled DNA fragments derived from cloned human λ constant genes (P.A.H., unpublished results). These were a 1.2-kilobase *Bam*HI-*Eco*RI fragment bearing the C_{λ} (Kern⁻Oz⁻) gene and a 0.8-kilobase *Bam*HI-*Hind*III fragment bearing the C_{λ} (Mcg) gene (Fig. 2, bottom). Because of the close amino acid sequence

Fig. 2 Detection of rearranged λ genes in λ -expressing human B cells. λ -Expressing B cells examined included the monoclonal λ light-chain-bearing B lymphocytes from patients (cases 1-6) with high-count chronic lymphocytic leukaemia, as well as four long-term λ -secreting Epstein-Barr virus-transformed normal human B-cell lines (cases 7, 8, 9, 10). Fibroblast cell cultures from cases 1, 2, 3 and spontaneous T-cell lines from cases 7 and 8 served as matched controls in the germ-line configuration. The two observed germ-line patterns of C_{λ} gene fragments are presented and referred to as type I and type II. As before, genomic DNA from all cells was digested with *Eco*RI, size fractionated by agarose gel electrophoresis, transferred to DBM paper and hybridized with ³²P-labelled combined C_{λ} probe. The C_{λ} probe (hatched bars) was a combination of the 1.2-kilobase embryonic *Bam*HI-*Eco*RI fragment containing the Kern⁻Oz⁻ C_{λ} gene and the 0.8-kilobase embryonic *Bam*HI-*Hind*III fragment containing the Mcg C_{λ} gene (as evidenced by nucleotide sequence analysis; P.A.H., unpublished results).

Fig. 3 Detection of λ genes in germ-line configuration in κ -expressing B cells. DNA obtained from the eight κ -expressing B cells shown in Fig. 1 and the available matched germ-line controls were digested with *Eco*RI, size fractionated by agarose gel electrophoresis, transferred to DBM paper and hybridized with the combined C_λ probe (described in Fig. 2). Cases 1–6 show type I germ-line λ genes; case 8, type II germ-line λ genes. We presume that case 7 is heterozygous for both the 8- and 20-kilobase *Eco*RI site alleles, although no matched germ-line control was available for this B-cell line.

homology of the known human λ constant regions, the combined C_λ probe would be expected to cross-hybridize to all four of the C_λ genes. Analyses of *Eco*RI digests of 24 non-B-cell genomic DNAs (placenta, fibroblast and T cells), which were carried out to establish the germ-line pattern, demonstrated a genetic polymorphism in *Eco*RI endonuclease sites that produced two predominant fragment patterns (Fig. 2, germ-line lanes), one which yields 8-, 16.5- and 18-kilobase fragments and another which yields 16.5-, 18- and 20-kilobase fragments. Such polymorphisms, which seem quite common at this locus (P.A.H., unpublished), provide useful chromosomal markers for further genetic studies.

Keeping in mind that apparent alterations in the *Eco*RI fragment pattern at the λ locus might be due to these polymorphisms, we examined a number of human λ chain-expressing B lymphocytes. These included monoclonal B cells from six patients with chronic lymphocytic leukaemia and four normal human B-cell lines transformed by Epstein-Barr virus. *Eco*RI digests of all 10 λ -expressing B cells showed at least one rearranged C_λ allele that was not seen in the matched non-B cells (either fibroblasts or T cells) from the same individual. Three of the B cells displayed double rearrangements that could be used to establish the order of the λ genes in chromosomal DNA. This was done by noting that in three cases (1, 3 and 8; Fig. 2), the 8-kilobase *Eco*RI fragment was lost in a double rearrangement of λ alleles, while the 16.5- and 18-kilobase fragments were preserved. Because V/J recombination occurs to the 5' side of an expressed constant region and involves deletion of DNA between V and J regions^{12,13,19}, the retained constant λ genes must be 3' to those on the 8-kilobase fragment.

λ genes are in the germ-line configuration in κ -expressing B cells

The arrangement of the λ light-chain genes in the eight human κ light-chain-expressing B cells analysed above is shown in Fig. 3. In all eight of the κ -expressing B cells, the *Eco*RI λ gene-

containing fragments remain in the germ-line configuration. Note that case 7, which demonstrates both the 8- and 20-kilobase *Eco*RI restriction fragments, seems to be heterozygous for the type I and type II polymorphic gene configurations.

κ genes are deleted or rearranged in λ -expressing B cells

In clear contrast to the germ-line arrangement of λ genes in κ -expressing cells, both C_κ alleles are deleted in all six λ -expressing leukaemic B cells (*Bam*HI digest shown in Fig. 4). In addition, both C_κ alleles were deleted in three of the four λ -expressing B-cell lines. In the other case, one κ allele was rearranged while the other was deleted (case 10, Fig. 4). Although case 10 was a long-term cell line, it was not physically cloned. The finding of C_κ gene deletions in the nine λ -expressing B cells was confirmed in the *Eco*RI digests of genomic DNA from these same cells (data not shown). In contrast to the observed deletion in the clonal B cells, the C_κ gene was present in the germ-line configuration in *Bam*HI and *Eco*RI digests of DNA from matched (same individual) T cells or fibroblast lines, demonstrating that the κ gene deletions are apparently limited to the λ -expressing B cells (Fig. 4).

The κ gene deletions usually include the J segment

To examine the possibility that the C_κ deletion could extend to J and V region coding segments, conceivably involving the entire chromosome, we prepared probes corresponding to four J_κ segments and to a V-region gene (see Fig. 5) and tested for complementary sequences in each cell line. In the representative case shown (Fig. 5), C_κ and J_κ coding segments fail to hybridize to a complementary sequence within the λ -expressing B cell, indicating that the deletion has included the J_κ segment. However, the V-region probe detects complementary fragments indicating that this V region family has not been included in the deletion of C_κ and J_κ . The presence of V_κ sequences demon-

Fig. 4 C_κ gene deletion or rearrangement in λ -expressing B cells. The 10 λ -expressing B cells (B) and their available matched germ-line control fibroblasts (Fib) or T cells (T) were *Bam*HI-digested as before and then hybridized with the ³²P-labelled 2.5-kilobase *Eco*RI C_κ gene fragment (see Fig. 1). We see very faint bands present in several cases of chronic lymphocytic leukaemia B cells that are not evident in the figure. These represent the germ-line C_κ segments present in the 3–15% contaminating monocytes and T cells found in leukaemic B-cell preparations and are absent from all the cultured cell lines.

strates that the deletion event is localized and does not represent merely a loss of the chromosome bearing the κ locus. Identical studies of the remaining deletion examples gave identical results with a single exception—in one case, a J_{κ} was present, but in a rearranged configuration (data not shown). This exception nevertheless suggests that such deletions can occur from various points in the chromosomal DNA.

Several gene configurations can account for allelic and isotype exclusion

It is already clear from various analyses in the mouse that a significant proportion of κ light-chain-gene rearrangements are aberrant; that is, they create non-functional or invalid genes, genes incapable of producing normal light-chains⁵⁻⁸. Multiple rearrangements are not uncommon in mouse myeloma cells^{5-8,14-18}. Some of these rearrangements seem to depend on the normal V/J recombination mechanism that occasionally creates a nonsense sequence and, hence, a null gene^{5,6}. Other rearrangements do not seem to depend on V/J recombination, but involve additional mechanisms (conceivably those analogous to the heavy-chain switch) that produce aberrant recombinants between regions that may or may not encode authentic V or J segments^{7,8}. One such rearrangement actually involves a

Fig. 5 Extent of κ gene deletion in λ -expressing B cells. A comparison of C_{λ} , C_{κ} , J_{κ} and V_{κ} gene segments in a representative λ -expressing B cell (case 7, Fig. 2) and its matching (same individual) T cell is shown. The probes are shown as hatched bars under each map. ^{32}P - C_{λ} and ^{32}P - V_{κ} (see below) probes (shown in figure) were hybridized to the *Eco*RI digests of B cells and available germ-line controls. ^{32}P - J_{κ} and ^{32}P - C_{κ} probes were hybridized with the *Bam*HI digests of the same cells. The V_{κ} gene probe was the 1.6-kilobase *Hpa*II fragment derived from the active V_{κ} - J_{κ} recombinant of the κ -expressing cell line RPMI 6410¹⁰. This fragment includes 63 bases of the 5' variable region corresponding to the first framework (sequence not shown). The amino acid translation of the nucleotide sequence yielded a protein sequence identical to that obtained for the human light-chain MAG²³ which is a member of κ subgroup II²⁴. The J_{κ} gene probe was a 1.7-kilobase germ-line (embryonic) *Cfo*I restriction fragment containing four human J_{κ} segments. The C_{κ} probe is described in Fig. 1 legend; the C_{λ} probe, in Fig. 2 legend.

recombinational 'hotspot' between the mouse J and C regions that is complementary to an extension of the small palindromic sequence thought to be involved in V/J recombination⁷. It is not known what proportion of DNA rearrangements during B-cell development result in the formation of an active gene, but it is conceivable that all light-chain alleles of both classes will occasionally rearrange in a single cell to form non-functional genes. Such cells may not survive as expanded clones. However,

Fig. 6 Developmental scheme of ordered light-chain gene rearrangements in pre-B cells. The genotype of each intermediate cell is indicated within the nucleus, while the predicted arrangement of *Bam*HI(κ) or *Eco*RI(λ) fragments is shown diagrammatically below each active cell. The overall scheme of lymphocyte development is not shown in order to focus on those stages concerned with light-chain gene activation. The initial cell in this scheme represents a pre-B cell already committed to the expression of cytoplasmic μ heavy chain. The expected germ-line configuration of the κ (κ^0) and λ (λ^0) light-chain gene fragments is shown schematically below. Light-chain gene rearrangements then take place (either productively or aberrantly) in a sequence such that rearrangements progress generally from the κ to the λ light-chain genes. Gene rearrangements cease to occur as a result of the formation of an active light-chain gene and synthesis of a viable light-chain product as suggested by Alt *et al.*⁹. The genotypes and representative light-chain gene fragment configurations for each of the four light-chain-producing cell types are shown. Bold faced lines represent the active allele; a dotted line represents either a deleted or aberrantly rearranged allele. Genotype superscripts signify the following: 0, germ-line configuration; +, viable V-J joining event; X, aberrant rearrangement or deletion. Gene fragment patterns consistent with each active cell type have been noted in this study. In addition, the scheme predicts a population of B-cell precursors with non-rearranged or only one aberrantly rearranged gene. It also predicts a population of cells incapable of forming valid light-chains, having 'spent' their germ-line genes on invalid recombinations.

in a B cell in which a functional light-chain gene has been formed, it is reasonable to suggest that germ-line or aberrantly rearranged genes account for allelic exclusion. Perry *et al.*⁴ have emphasized that non-viable gene rearrangements may have a significant role in this process, whereas Joho and Weissman³ have interpreted their studies of κ gene arrangements in circulating lymphocytes so as to suggest that the excluded allele is most often in the germ-line configuration. Similar arguments can be made to account for isotype exclusion. The present study suggests that both aberrantly rearranged genes and genes that remain in the germ-line configuration are responsible for these types of exclusion.

The order of light-chain gene rearrangements

The fact that λ genes seem to remain in the germ-line configuration in κ -producing cells while κ genes are rearranged or (more often) deleted in λ -producing cells allows us to suggest a hierarchy of events involved in light-chain activation. If we simply assume that κ gene rearrangement usually precedes that of λ , and if we accept the useful proposal of Alt *et al.*⁹ that the appearance of a functional light-chain product precludes additional light-chain-gene rearrangements, we can place each of our B cells along the developmental scheme shown in Fig. 6. In this scheme it is proposed that a pre-B cell undergoes either a valid or a non-functional κ rearrangement. If the initial rearrangement is valid, the clone expands and the gene arrangement $\kappa^+/\kappa^0/\lambda^0/\lambda^0$ (where the superscripts + = valid, 0 = germ-line, X = aberrantly rearranged or deleted) is observed. If the initial κ rearrangement is non-functional, a second κ rearrangement occurs and, if valid, the clone expands and the arrangement $\kappa^X/\kappa^+/\lambda^0/\lambda^0$ is observed. If both κ alleles are aberrantly rearranged or deleted, the next rearrangement involves one of the λ alleles which, following the cascade diagram shown in Fig. 6, could go on to produce all the possible combinations of valid and non-functional genes shown in the figure. An intermediate population of pre-B cells which have no active light-chain genes

is predicted by this scheme, including a terminal cell type in which all light-chain genes are aberrantly rearranged or deleted. Each active configuration predicted by this scheme occurs among the B cells we have examined. On the other hand, if λ rearrangement were to precede that of κ or to occur at the same relative frequency as κ , then we should have seen λ genes rearranged in κ -producing cells. We have not observed this situation in any of the κ -producing cells examined. A sequential process of light-chain gene rearrangement, which seems to involve the frequent deletion of C_κ genes and a joining order that proceeds from κ to λ , can be thought of as an error-compensating cascade that finally creates an active gene while experimenting with the flexible joining rules that allow optimum diversification.

Why is the κ constant region deleted?

The arguments outlined above do not deal with the finding that the κ constant region genes are entirely deleted in 9 of the 10 λ chain-producing cells analysed. Such deletions obviously involve recombination sites not ordinarily involved in V/J recombination. For example, the deletion of C_κ may be the result of an aberrant recombination event between a V_κ gene and a recombination site which lies 3' to the κ constant gene. Alternatively, this deletion might represent secondary recombinational events that follow the formation of valid or invalid κ genes. But why has the gene disappeared with such a high frequency? One possibility is that this deletion is a normal step in

the progress of light-chain recombination, perhaps a step for the elimination of inactive κ genes. This seems unlikely in view of the fact that cells with active κ genes seem to tolerate the presence of invalid allelic recombinants. It is more likely that elimination of the κ gene is closely related to λ gene rearrangement, either as an effect or as a cause. The possibility that λ rearrangement is necessary for κ gene deletion seems doubtful in view of the several examples of κ deletion in κ chain-producing B cells in which no λ gene rearrangement has occurred (Fig. 1, cases 5 and 8). Instead, one might imagine the formation of a positive control element by the κ deletion event which causes the onset of λ gene rearrangements. Alternatively, a negative control element preventing λ gene rearrangement might be eliminated by the κ deletion event. Our single example (Fig. 4, case 10) of a retained (but rearranged) κ gene in a λ -producing B-cell line does not rule out the negative control argument as the effect might be sensitive to gene dosage or the κ gene rearrangement may itself have been sufficient to eliminate the control element. In addition, because this human cell line is uncloned, we must consider the possibility that the rearranged κ gene might reside in a subpopulation of B cells that is not involved in λ chain production. The striking observation that κ constant region genes are consistently deleted or rearranged in λ -expressing B cells may, among other possibilities, indicate a potential coupling between λ chain activation and κ gene deletion, a recombination event that might have regulatory implications.

Aberrant rearrangements contribute significantly to the allelic exclusion of immunoglobulin gene expression

Christopher Coleclough, Robert P. Perry, Klaus Karjalainen & Martin Weigert

Institute for Cancer Research, Fox Chase Cancer Center, Philadelphia, Pennsylvania 19111, USA

A study of the organization of light- and heavy-chain immunoglobulin genes in mouse splenic B cells, spleen-derived hybridomas and plasmacytomas has unequivocally demonstrated that aberrant rearrangements are common during normal B-cell development. The results support a probabilistic model for allelic exclusion of immunoglobulin gene expression.

PHENOTYPIC expression of immunoglobulin genes depends on site-specific recombination events which bring the genetic elements encoding the immunoglobulin variable and constant regions within a single transcription unit. This is most easily appreciated in the mouse λ_1 light-chain gene system, in which an active gene is constructed by the precise fusion of the single V_{λ_1} gene with the single J_{λ_1} element residing 1.2 kilobases 5' of the C_{λ_1} gene¹. Although the mouse κ light-chain gene family is more complex, comprising some hundreds of V_κ genes and four functional J_κ elements, gene activation is essentially similar, requiring a single recombination event to fuse V_κ and J_κ ^{2,3}.

However, the construction of a functional μ heavy-chain gene seems to require two recombination events, which result in the fusion of three distinct genetic elements: V_H , D_H and J_H ^{4,5}.

Immunoglobulin gene expression exhibits allelic exclusion; that is, in each individual antibody-forming cell, only one of the pair of alleles at an immunoglobulin locus is expressed while the other is phenotypically silent. Similarly, the synthesis of κ and λ light chains in individual lymphoid cells is mutually exclusive. How is this achieved? Recently, we analysed the status of allelic κ genes in a large number of κ -secreting plasmacytomas⁶. In about half of the plasmacytomas examined, the phenotypically

Fig. 1 The extent of J_{κ} rearrangement in κ -bearing B cells. **A**, schematic map of the J_{κ} - C_{κ} region. Cloned hybridization probes are shown as hatched boxes. Plasmid pEC $_{\kappa}$ was constructed by insertion into pBR322 of the *EcoRI*-*Bam*HI fragment shown, which was derived from the 15.5-kilobase (kb) *EcoRI* fragment cloned in Charton 4A by Lenhard-Schuller *et al.*²³. IVS was isolated by *Hind*III-*Xba*I digestion of pEC $_{\kappa}$ and gel electrophoresis. Recombination involving the J_{κ} region will deplete the germ-line J_{κ} -containing *Hind*III fragment relative to the C_{κ} -containing fragment, and may be detected as a decrease in the J_{κ} / C_{κ} fragment ratio. Recombination 3' (right) of the *Hind*III site between J_{κ} and C_{κ} , however, is not detectable by this assay, as it depletes the germ-line J_{κ} and C_{κ} *Hind*III fragments to the same extent. **B**, a representative experiment. DNA samples prepared from 14-day BALB/c embryos²⁴, or from κ -bearing B cells were digested to completion with *Hind*III (Biolab), and various amounts (~0.5–8 μ g) electrophoresed through 0.8% neutral agarose gels, transferred to nitrocellulose paper²⁵ (Schleicher and Schuell), and hybridized to ³²P-labelled pEC $_{\kappa}$ plasmid DNA^{11,26}. Filters were exposed to X-ray film at

–70 °C, using an intensifying screen, for various periods; the one shown was exposed for ~10 h. The κ -bearing B cells were purified from BALB/c spleen cells. Suspensions of spleen cells were depleted of T cells by treatment with anti-Thy-1 and complement, and centrifuged through Ficoll-Hypaque (Pharmacia) to remove erythrocytes and dead cells. The B-cell-enriched preparation was labelled with rabbit antiserum directed against mouse κ constant region, counterstained with fluorescent-coupled goat anti-rabbit immunoglobulin and passed through the fluorescence-activated cell sorter (Becton-Dickinson, FACS II). **C**, densitometer tracings of representative tracks from Southern blot autoradiographs of embryo and B-cell DNA showing the marked reduction of the J_{κ} peak (right) in B-cell DNA. **D**, graphical estimation of the extent of J_{κ} rearrangement in B cells. Several exposures of the autoradiogram in **B** and another set of data from a similar experiment were scanned as in **C**. Comparison of multiple exposures of the same tracks showed that peak heights between 0.5 and 6 cm corresponded to the linear portion of the dose-response curve of the film. Data within this range were plotted as J_{κ} against C_{κ} ; each point is derived from an individual track. The least-squares best fit of the embryo data has a slope of 1.105; that of the B-cell data, 0.35. ○, Embryo DNA; ●, B-cell DNA.

silent allele was maintained in the germ-line context, whereas in the other half it had undergone some type of non-productive rearrangement. We concluded that imprecision intrinsic in the process of somatic recombination contributes significantly to the allelic exclusion of κ gene expression, and we proposed a model in which the status of the κ alleles is determined by the recombination frequency and the relative probabilities of productive as opposed to non-productive rearrangements^{6,7}. Our conclusion, which was supported by the results of other studies on the extent of J_{κ} ^{23,29,30} and J_{H} ³¹ rearrangement in myelomas and lymphomas, was based on the assumption that plasmacytomas are valid models of untransformed plasma cells. This assumption was questioned by Joho and Weissman⁸, who measured the extent of κ gene rearrangement in κ -expressing splenic B cells and concluded that non-productively rearranged κ genes are very rare or absent in normal lymphoid populations. However, their conclusion was based on a single determination and an arbitrary interpretation of their normalization data.

To settle this issue and to examine the general applicability of the probabilistic model we have made a detailed study of the extent of non-productive rearrangement of both light- and heavy-chain immunoglobulin genes in normal mouse splenic B cells, spleen cell-derived hybridomas and, for comparison, appropriate panels of plasmacytomas and B-cell lymphomas. Our results indicate that at least one out of three normal B cells contains a non-productively rearranged J_{κ} locus and that the silent J_{H} locus is rearranged in >80% of the B-cell population. We also provide evidence for extensive J_{κ} rearrangement in λ -producing cells in contrast to a paucity of J_{κ} rearrangement in κ expressors. These results demonstrate unequivocally that aberrant rearrangements are a common feature of normal B-cell development. Moreover, they support the idea that both class and allelic exclusion can be explained in terms of a probabilistic model of immunoglobulin gene rearrangement.

Non-productive rearrangement of κ genes occurs frequently in B cells

In monoclonal lymphoid lines, J_{κ} rearrangement is detected by observing a discrete J_{κ} -containing restriction fragment differing

from that found in embryo (germ-line) DNA. In contrast, one would not expect a discrete novel J_{κ} band in a Southern blot of DNA from the total splenic population of κ -expressing B cells because the many different V-J combinations would result in a diverse array of fragments of varying sizes. The extent of J_{κ} rearrangement in this population can, therefore, be calculated from the relative decrease in intensity of the embryo-type J_{κ} band. We needed a strategy to estimate precisely this decrease, using controls and quantitative measurements internal to the experiment. Figure 1A shows a map of the C_{κ} region. It can be seen that a *Hind*III digest of embryo DNA when probed on a Southern blot with a plasmid containing an appropriate *EcoRI*-*Bam*HI fragment, pEC $_{\kappa}$, reveals two major fragments. The larger of these, ~4.5 kilobases, contains the C_{κ} gene, while all the J_{κ} elements are contained within a fragment of ~2.9 kilobases. As these fragments overlap the pEC $_{\kappa}$ probe to about the same extent, their autoradiographic intensities should be roughly equivalent. That this is indeed the case was verified (Fig. 1B–D) by measurements of varying amounts of embryo DNA. As shown in Fig. 1D, a plot of the intensity of the J_{κ} band versus that of the C_{κ} band gives a straight line with a slope of ~1. For these determinations, autoradiographic exposure times were confined to a range in which the densitometric peak heights were directly proportional to the amount of radioactivity emitted. In contrast, when a similar set of measurements were made with the DNA of κ -expressing splenic B cells, the intensity of the J_{κ}

Table 1 Extent of J_{H} gene rearrangement in splenic B cells

Sample	C_{κ} gene dosage (μ g embryo DNA equivalent)	J_{H} gene dosage (μ g embryo DNA equivalent)	% J_{H} genes unrearranged	% B cells with both J_{H} genes rearranged*
B1	10.0	~0	~0	~100
B2a	8.0	0.5	6.25	87
B2b	7.5	0.7	9.3	81

The C_{κ} and J_{H} gene dosages were estimated from Fig. 5B.

* Assumes each cell has at least one rearranged J_{H} .

band was ~ 0.35 that of the C_κ band as judged by the slope of the J_κ versus C_κ plot. If all the B cells had contained one productively arranged and one unrearranged J_κ locus, the slope would have been 0.5. Our data demonstrate that this is not the case (confidence limit >0.95); rather they indicate that about one-third of the cells contain two rearranged J_κ loci, one of which would presumably be non-productive with respect to κ -chain production. This fraction is actually a minimum estimate because the above analysis is sensitive only to those rearrangements which result in a loss of the 2.9-kilobase J_κ fragment and retention of the 4.5-kilobase C_κ fragment, whereas some non-productive rearrangements could conceivably involve the loss of both fragments.

λ_1 genes are infrequently rearranged in κ -expressing cell lines but κ genes are often rearranged in λ -producing cell lines

We wished to assess whether the probabilistic model which we applied to allelic exclusion at κ loci is also valid for light-chain class exclusion. That is, can both κ and λ loci be regarded as elements competing for mutually exclusive expression in a single pool of B cells? If this is the case, then non-productive gene rearrangement would be evident in cell lines producing either κ or λ light chains.

Initially we determined the status of λ_1 genes in a panel of κ -producing plasmacytomas. Southern blots of *Eco*RI-digested embryo DNA probed with a λ_1 cDNA-containing plasmid exhibit four bands at 8.6, 4.8, 3.5 and 2.5 kilobases (Fig. 2). Brack *et al.*¹ have identified the largest three as containing C_{λ_1} , V_{λ_1} and V_{λ_2} , respectively. We do not know which hybridizing element is contained within the 2.5-kilobase band; possibly it is related to the λ_{III} locus⁹. Each of the four λ_1 -producing plasmacytomas examined showed a novel band at 7.4 kilobases, characteristic of the fused V_{λ_1} - C_{λ_1} gene¹. There is some evidence of additional λ gene rearrangement: Y5444 seems to lack an unrearranged allelic C_{λ_1} gene and J558 lacks an unrearranged

allelic V_{λ_1} gene. When DNA from 14 κ -producing plasmacytomas was similarly probed, all revealed the germ-line set of λ bands; one cell line, PC2960, showed one additional band that is different from the productive V_{λ_1} - C_{λ_1} hybrid. One λ gene has been rearranged non-productively in this cell line, but without further analysis, we cannot say which. Clearly, however, λ gene rearrangement is rare in κ -producing cells.

We performed the complementary experiment, determining the status of κ genes in λ -producing cells, at first with the four λ plasmacytomas used above. In no case could we find a germ-line-type κ gene (not shown). To extend our analysis, we decided to use λ -producing hybridomas, which can be produced in reasonable numbers and, moreover, can be assayed soon after induction, minimizing the time spent in serial passage. The use of cultured hybridoma lines also eliminates any possible contamination by DNA of non-lymphoid origin. Certain strains of mice, in response to primary immunization with nitrophenyl chicken globulin (NPCG), produce antibodies in which λ light chains are frequent¹⁰. We produced a large number of hybridomas from spleen cells after primary immunization of CB.17 mice with NPCG. After cloning and serological characterization, we analysed DNA from 12 λ -secreting hybridomas. DNA was digested with *Hind*III and processed as above, this time probing with the *Hind*III-*Xba*I fragment, IVS. As shown in Fig. 1A, embryo DNA yields a 2.9-kilobase fragment that hybridizes with this probe; rearrangement at or close to any J_κ will substitute this with a novel fragment. Our results are shown in Fig. 3. Ag8.653, the myeloma partner used to produce hybridomas, has a strong band at ~ 6.5 kilobases, which is maintained in all the hybridomas. Clearly, rearrangement at J_κ is frequent in these hybridomas. Four hybridomas, *d*, *e*, *f* and *g*, showed bands similar in mobility to that characteristic of unrearranged C_κ genes. A second analysis, including an embryo marker, shows that only the fragment from hybridoma *f* is actually coincident with the embryo-type fragment (Fig. 3B). To verify that hybridoma *f* does indeed contain a non-rearranged κ gene, we performed a similar analysis with DNA that was digested with *Bam*RI and *Bam*HI plus *Eco*RI. Hybridoma *f* continues to

Fig. 2 Southern blot analysis of the λ loci in a series of λ - and κ -secreting plasmacytomas. Aliquots (10 μ g) of DNA from the sources indicated were digested with *Eco*RI, electrophoresed through a 0.7% agarose gel, transferred to nitrocellulose and hybridized with ^{32} P-labelled plasmid B1, which contains V_{λ_1} and C_{λ_1} sequences derived from H2020 mRNA¹. Tracks marked BALB contained 10 μ g 14-day BALB/c embryo DNA. kb, Kilobase.

Fig. 3 J_{κ} rearrangement in λ -producing hybridomas. Hybridomas specific for NPCG were produced as described elsewhere¹⁰ by fusion of immune spleen cells with Ag8.653 cells²⁷. After selection for drug-resistance phenotype and antigen binding specificity, those hybridomas secreting λ light chains were revealed by radioimmunoassay. **A**, DNA from the myeloma parent cell line Ag8.653 and from each of 12 individual cloned λ -producing hybridomas (*a-l*) was digested with *Hind*III, electrophoresed through 0.7% agarose and probed with ³²P-labelled IVS (see Fig. 1A). Ag8.653 DNA shows strong hybridization to a fragment ~6.5-kilobases long, and this is maintained in all hybridomas. The weak band at 4.5 kilobases is due to slight contamination of the electrophoretically purified IVS probe with a C_{κ} fragment, which hybridizes to the 4.5-kilobase C_{κ} *Hind*III fragment and thus is maintained in all cell lines. The J_{κ} region in its germ-line context is revealed as a 2.9-kilobase fragment. **B**, four hybridomas, *d-g*, which exhibited J_{κ} *Hind*III fragments with mobilities close to that characteristic of the germ-line J_{κ} region, were re-assessed relative to BALB/c embryo DNA. *Hind*III digests were analysed by gel electrophoresis and Southern blotting as above. **C**, hybridoma *f* was further analysed to confirm that it contained a non-rearranged J_{κ} region; *f* has a fragment with identical mobility to that of the germ-line fragment after both *Bam*HI digestion and *Bam*HI-*Eco*RI double digestion.

display a fragment indistinguishable in size from the embryo-type κ gene fragment (Fig. 3C).

Thus, the prevalence of rearranged over non-rearranged κ genes in λ -producing lymphoid lines is high but not absolute. Of the 15 distinct J_{κ} gene contexts (counting *b* and *c* as one clone; see below) discovered in these 12 hybridomas, one is germ line and 14 are rearranged. Three of the hybridomas show only one J_{κ} fragment; two show no hybridization other than to the Ag8 fragment. This could be due either to chromosome segregation or to the specific deletion of this region. Interestingly, two clones, *b* and *c*, show identical patterns of J_{κ} context, and are also identical in heavy-chain gene context (not shown). We are certain that these are independent clones; thus they probably derive from the same B cell, clonally expanded *in vivo*.

J_H rearrangement usually occurs in both heavy-chain alleles in plasmacytomas and normal B cells

We set out to evaluate the incidence of rearrangement in the silent J_H locus by examining the context of the J_H cluster in established lymphoid lines and splenic B cells. The J_H elements are contained in an *Eco*RI fragment ~6.2 kilobases long (Fig. 4A). Recombination within or near the J_H cluster should produce a novel *Eco*RI fragment which could be revealed by hybridization of an appropriate recombinant plasmid, pJ11. An application of this analysis to a series of plasmacytomas is shown

in Fig. 4B. As all the plasmacytomas synthesize a heavy chain, at least one novel *Eco*RI fragment is expected in each case. In fact, most, 15 out of 20, show two distinct novel *Eco*RI fragments, as do the two lymphomas 38C and 70Z, demonstrating frequent rearrangement of the silent allelic J_H cluster. All plasmacytomas which were grown as subcutaneous tumours show some, mostly faint, hybridization to an embryo-type fragment which presumably derives from contaminating host cells, as noted before^{6,11}. Rearrangement of both J_H alleles was also observed by Cory and co-workers³¹ in a similar analysis of a myeloma and several lymphoma lines. Three examples, PC2960, PC7043 and PC6308, show strong hybridization to an embryo-type fragment and only a single novel fragment. We have further analysed PC7043 and PC6308 using an *Eco*RI-*Sac*I digest, which yields a J_H fragment of ~3 kilobases. Both plasmacytomas yield a J_H band coincident with that of the embryo type (data not shown). Thus, we note that, although rearrangement of the silent allelic J_H cluster is frequent in lymphoid lines, it is not a universal occurrence.

In our first set of experiments with splenic B cells purified on a fluorescence activated cell sorter (FACS), we noted that, whereas *Eco*RI digestion of B-cell DNA yields a distinct C_{μ} fragment, no discrete band is obtained using *Kpn*I¹². Because the *Kpn*I site upstream of C_{μ} is 5' distal to the J_H cluster, this result suggested relatively frequent J_H recombination in B cells. Here we refine and quantify those observations.

As discussed above for J_{κ} rearrangement, the extent of J_H rearrangement in the splenic population of surface IgM-positive

Fig. 4 J_H gene rearrangement in lymphoid lines. **A**, restriction map of C_μ gene and J_H region. Black areas indicate protein coding elements. Hatched boxes indicate sequences represented in the C_μ probe: the cDNA plasmid pμ(3741)⁹ and the J_H probe: the genomic DNA plasmid pJ11¹³. The map was compiled from refs 13 and 28 and our own observations. Not all *SacI* sites are shown. **B**, 10 μg of DNA prepared from each indicated source was digested with *EcoRI* and electrophoresed through 0.75% agarose, transferred to nitrocellulose and hybridized with ³²P-labelled pJ11. All cell lines are from NZB mice, except M104E and J558, which are from BALB/c mice, 38C from a C3H mouse, and 70Z which derives from a (C75BL/6 × DBA/2) F₁ hybrid. The mobility of non-rearranged J_H restriction fragments from these strains is identical, thus all tracks are comparable with the BALB/c embryo tracks. Tracks labelled M contained 1 μg *EcoRI*-digested λ phage DNA and 3 pg each of *EcoRI*-treated, and *EcoRI* plus *SacI*-digested pMB9 DNA. The latter species are revealed by hybridization with recombinant plasmid probes and appear on the autoradiograph as 5.8- and 4.8-kilobase fragments.

B cells must be calculated from the relative decrease in intensity of the embryo-type J_H band. We again used hybridization to the constant-region gene fragment to control for and quantify the extent of hybridization to the neighbouring J-region fragment. We wished to separate the C_μ gene from its labile 5' flanking region¹³ to avoid the possibility that any rearrangement in this region could lead to an underestimation of C_μ gene dosage. This was achieved using *SacI*, which cleaves in the intron between $C_{\mu 1}$ and $C_{\mu 2}$ exons. A *SacI*-*EcoRI* double digestion yields a 5.1-kilobase C_μ fragment and a 3-kilobase J_H fragment from embryo DNA (Fig. 4A).

Our analysis of splenic B cells is shown in Fig. 5A. Two different samples of B-cell DNA were analysed, one in duplicate, loading ~6 to 8 μg of DNA per track, together with two sets of a titrated series of embryo DNA. B-cell DNA shows a striking deficit of the J_H band relative to embryo DNA, indicating extensive rearrangement of the J_H region. One sample (B1) shows no distinct J_H band at all, whereas the other duplicate samples (B2a, b) show very faint bands over an elevated background.

Because of the large difference in intensity of the J_H and C_μ bands it was not possible to select a range of autoradiographic exposures for which both bands were on the linear portions of their dose-response curves. Therefore, we had to use a different method of calculating the extent of J_H rearrangement from that used for the J_κ measurements. By varying the exposure time of the autoradiograph and scanning the tracks on a densitometer, we obtained calibration curves relating C_μ of J_H peak height to the input amount of embryo DNA (Fig. 5B). By reference to these curves we used the measured peak heights to estimate the apparent C_μ gene and J_H gene dosage as equivalent μg total embryo DNA input (Table 1). The extent to which apparent J_H gene dosage is less than apparent C_μ gene dosage in B-cell DNA equals the extent of J_H rearrangement. Assuming that all IgM-expressing B cells must have one rearranged J_H region, we calculated the per cent of cells in each sample which have rearranged their silent J_H allele as: B1 ~100%, B2a 87% and B2b 81%. The persistence of a small proportion (~15%) of cells with an unrearranged J_H locus is consistent with the results of the plasmacytoma survey described above.

Discussion

These results clearly demonstrate that the aberrant rearrangements previously observed in transformed lymphoid cells also occur in normal B cells, and consequently that the recombination process responsible for the formation of functional immunoglobulin genes is error prone. Thus, when recombination events occur during B-lymphocyte maturation, a germ-line locus (Ig⁰) may be rearranged to form either a functional (Ig⁺) or a non-productive (Ig⁻) immunoglobulin gene. Detailed analyses of κ genes have revealed several types of non-productive rearrangements: those involving recombination at a pseudo J site, which lacks a proper RNA processing signal^{6,14,15}, those involving joining errors, which create translational stop codons^{16,17}, and those which extinguish transcription^{6,7}, possibly due to the selection of a non-functional (pseudo?) V-region segment.

We have suggested that the status of immunoglobulin alleles depends principally on their recombination frequency, which may vary over the course of B-cell maturation, and the relative probability of productive as opposed to non-productive rearrangements⁷. With appropriate values of these parameters, this probabilistic model should predict the ratio of Ig⁰/Ig⁺ to Ig⁻/Ig⁺ genotypes in a particular population of lymphoid cells. Our previous studies of κ -expressing plasmacytomas indicated a 1:1 ratio of κ^0/κ^+ to κ^-/κ^+ genotypes, whereas our current measurements of κ -expressing splenic B cells indicates a ratio of ~2:1. If this discrepancy actually reflects a difference between plasma cells and B cells, it would suggest that κ rearrangement can still occur during clonal expansion of B cells, although at a greatly diminished frequency compared with pre-B cells. Our estimate of 33% non-productive rearrangement in B cells is in marked contrast to the very low level claimed by Joho and Weissman⁸. However, when their single measurement was normalized with their rDNA data, we calculated 26% non-productive rearrangement, which is not significantly different from our more accurately determined value.

The high frequency of κ rearrangement in λ expressors and the rarity of λ rearrangement in κ expressors suggest that the recombination frequency is in part determined by the total

number of V and J elements that can participate in recombination, which in the mouse would greatly favour κ over λ . Furthermore, the fact that a κ^0 locus is occasionally retained by a λ expressor and a λ^- locus is occasionally present in a κ expressor is consistent with a probabilistic model which views the genes for both classes of light chain as equivalent candidates for productive or non-productive rearrangement. This fact is not easily accommodated by models which postulate a strictly sequential sampling of the κ and λ gene pools¹⁸.

If we consider the formation of a productive light-chain gene as the prime determinant of the developmental transition from pre-B to B cell¹⁹, then the composition of κ genotypes in λ -expressing spleen cells should reflect the steady-state distribution in pre-B cells at the time of this transition. Our results indicate a high proportion of κ^-/κ^- genotypes in these pre-B cells. For this to be compatible with a 2:1 ratio of κ^0/κ^+ to κ^-/κ^+ genotypes in B cells we need to postulate that the recombination frequency is greatly reduced after the formation of a productive light-chain locus. Such a supposition seems reasonable as the production of light chains allows the cell to display surface immunoglobulin²⁰ which presumably triggers

gross morphological and biochemical changes associated with the pre-B to B cell transition. This effective stabilization of genotypes by a productive rearrangement would effectively ensure the allelic exclusion of light-chain gene expression by diminishing the likelihood of $\kappa^0/\kappa^+ \rightarrow \kappa^+/\kappa^+$ transitions. A similar suggestion was recently made by Alt *et al.*¹⁸.

Our analysis of the heavy-chain (J_H) locus indicates a high frequency of non-productive rearrangement, with >80% of splenic B cells having μ^-/μ^+ genotypes. Yet the fact that a small but definite subpopulation have μ^0/μ^+ genotypes is consistent with the probabilistic nature of the recombination process. The difference in frequency of non-productive rearrangements between heavy- and light-chain genes may be related to the more complex structure of the heavy-chain locus, which requires at least two recombinational events (V_H to D_H and D_H to J_H) to produce a functional genetic unit. Lack of function may be due to an error in the D_H - J_H recombination, an error in the accompanying V_H - D_H fusion, or even the lack of a V_H - D_H recombination. In the latter case, the non-productive locus might represent an intermediate which could eventually undergo further rearrangement.

Fig. 5 J_H gene rearrangement in splenic B cells. A, B-cell-enriched fraction prepared as described in Fig. 1 legend was stained with fluorescein-coupled rabbit anti-mouse IgM and the surface IgM-positive fraction purified by FACS. The proportion of IgM-bearing cells in the final cell sample was estimated to be >98%. DNA was prepared from these cells and its concentration roughly estimated by visual inspection of ethidium bromide fluorescence of an aliquot compared with that of DNA of known concentration. B-cell DNA was digested sequentially with *SacI* and *EcoRI* and an estimated 6–8 μ g electrophoresed through 0.8% agarose. Two different samples of B-cell DNA were analysed, one of them in duplicate (B1; B2a, B2b). A titrated series of BALB/c embryo DNA was similarly analysed, in duplicate, loading 1, 2, 4 and 6 μ g as shown. Hybridization of the Southern blot to a mixture of ³²P-labelled plasmids p μ (3741)⁹ and pJ11 revealed the C_μ gene and the J_H region as fragments of 5.1- and 3.0-kilobases, respectively. Three exposures (20, 40 and 100 h) of the autoradiograph were developed. The entire 40-h exposure is shown, with the central five tracks (the three B-cell samples flanked on the left by 6 μ g and on the right by 1 μ g embryo DNA) of the 20- and 100-h autoradiographs shown as inserts on the lower left and lower right, respectively. B, the autoradiographs were scanned on a densitometer and peak heights measured. Peak heights of the C_μ fragment in embryo DNA from the 20-h autoradiograph were plotted against μ g input DNA to give a calibration curve linear at large DNA inputs, which we could use to estimate B-cell DNA input from C_μ peak height as shown. The curve relating embryo DNA input to J_H peak height on the 100-h autoradiograph is linear at small DNA inputs, and was used to estimate B-cell J_H gene dosage. ●, Embryo DNA; △, B-cell DNA.

A higher intrinsic recombinational frequency for heavy-chain compared with light-chain genes could explain why rearrangement of heavy-chain genes precedes that of light-chain genes during B-cell ontogeny^{21,22}. The fact that a relatively high proportion of the heavy-chain gene rearrangements are non-productive could account for the allelic exclusion of heavy-chain expression, for it would predict that most cells in which a $\mu^0 \rightarrow \mu^+$ transition occurs would already have experienced a $\mu^0 \rightarrow \mu^-$ on the other allele. This explanation is compatible with the idea that both heavy- and light-chain genes use the same recombinational machinery^{4,5}, and that this machinery remains essentially intact on formation of a functional heavy-chain gene. This seems reasonable because there are apparently no gross phenotypic changes in μ -expressing pre-B cells before the creation of a functional light-chain gene. Thus, allelic exclusion

of immunoglobulin gene expression is viewed as being due principally to recombinational errors in the case of heavy chains, and to a combination of errors and phenotypic alteration in the case of light chains.

We thank K. Marcu for the pJ11 plasmid, R. Riblet and J. Brill for many DNA samples, J. Haimovich for lymphoma DNA, B. Subbarao for fluorescent antibody and R. Overton for assistance with use of the FACS. The research was supported by a NSF grant, NIH institutional grants, a fellowship to K.K. from the EMBO and an appropriation from the Commonwealth of Pennsylvania.

Note added in proof: After submission of this article another observation of frequent rearrangement of the non-expressed J_H allele in normal B cells was reported³².

Cyclotron and annihilation lines in γ -ray bursts

E. P. Mazets, S. V. Golenetskii, R. L. Aptekar',
Yu. A. Gur'yan & V. N. Il'inski

A. F. Ioffe Physico-Technical Institute, Academy of Sciences of the USSR, 194021 Leningrad, USSR

Venera 11 and Venera 12 have detected emission and absorption lines in the energy spectra of many γ -ray bursts. The similarity between the spectral features observed during different events reveals the similarity in physical conditions and processes which occur within the burst sources. These lines are the most convincing evidence that the γ -burst sources contain neutron stars with a strong magnetic field. We present here results of a comprehensive analysis that included weaker bursts, which indicate that the presence of lines in the γ -burst spectra, in particular of absorption lines in the region 30-70 keV is a characteristic rather than an exceptional feature.

The investigation of lines in cosmic X-ray and γ -radiation is important, and has been reviewed elsewhere^{1,2}. γ -ray line radiation is characteristic of nuclear processes, however, in certain conditions, lines can be produced in the astrophysical plasma by radiative processes^{3,4}. Lines in the plasma radiation can be closely associated with the presence of superstrong gravitational and magnetic fields in sources such as degenerate dwarfs and neutron stars. The magnetic bremsstrahlung at the cyclotron frequency $\omega_H = eH/mc$ at fields $H > 10^{12}$ Oe already lies in the hard X-ray range. Pair production in the hot magnetized plasma may be a powerful source of positrons. The positron annihilation radiation produced near the surface of a neutron star should undergo a substantial gravitational redshift. Observations of these effects could provide a means for reliable determination of the gravitational and magnetic fields in the sources.

Cyclotron radiation in the X-ray range was first observed⁵ as the 58-keV line in the spectrum of Her X-1; the 73-keV line in the Crab spectrum may have the same nature⁶. It is thought that the redshifted annihilation line was observed⁷ among other lines in a transient event on 10 June 1974 and in the emission from the Crab nebula region⁸. However, not all of these pioneering

results are reliable²; in particular, the spectral features from the Crab nebula have not shown up in other observations therefore independent confirmation is needed.

Energy spectrum studies and the search for lines are also important in understanding the nature of the γ -bursts. In the Konus experiment carried out on Venera 11 and Venera 12 spacecraft during 1978–80 (ref. 9) energy spectra of ~ 150 γ -ray bursts in the 30 keV–2 MeV range were obtained, and the very first observations¹⁰ revealed lines in the spectra of some bursts. A redshifted annihilation line was clearly observed at 430 keV in the spectrum of the 5 March 1979 burst produced by a flaring X-ray pulsar¹¹. A broad emission feature was detected at 300–800 keV in the spectrum of a strong γ -burst on 19 November 1978 (ref. 9). A germanium detector on ISEE 3 revealed this as two lines at ~ 420 and 740 keV which were interpreted as the strongly redshifted 511-keV annihilation line and 847-keV iron line, respectively¹². Our subsequent measurements showed the presence of emission and absorption lines in several strong γ -bursts¹³.

The most typical examples of γ -burst spectra containing lines are shown in Figs 1–3. (More information on these events is given in refs 14, 15.) Eight consecutive measurements of the energy spectrum were made during each event, each lasting 4 s. Thus between 1 and 8 spectra were obtained for each burst, depending on its duration. The statistical accuracy of an individual spectrum of a weak event may be insufficient for line resolution, in which case, individual spectra are added together. This summation can also be used if no noticeable evolution of the spectrum is observed in the course of a burst.

Figure 1a shows the spectrum of a long intense event on 7 March 1979. Here the spectral distribution in the continuum, just as in most of the other bursts, fits the $dN/dE \propto$

$E^{-1} \exp(-E/kT)$ law typical for radiation from a hot, optically-thin plasma. An absorption line can be clearly seen at ~ 45 keV remaining visible in all the measured spectra. The line is assumed to result from absorption of the burst radiation at the cyclotron frequency ω_H in the outer, colder regions of the plasma in a strong magnetic field. The resonance is associated with the change of state of the electron in a magnetic field, its transition to the next Landau level involving the absorption of an energy $\Delta E = \hbar\omega_H = \hbar eH/mc$.

The spectrum of the 1 November 1979 burst is shown in Fig. 1b, c. In contrast to the 7 March 1979 event, the absorption line is observed here only at the initial burst stage (Fig. 1b). At the later stage (Fig. 1c) the line disappears—an evolution typical of many other bursts which may be associated with the heating of the absorption region during the burst development. The increase in emission at the cyclotron frequency in this region due to heating can cancel absorption in the spectrum of the γ -burst. In the 1 November 1979 burst the spectral distribution in the continuum also undergoes evolution. The spectrum becomes harder and the temperature kT increases from 240 to 480 keV.

An interesting feature of the absorption line in the spectrum of the 1 November 1979 event is an intensive wing at lower energies which causes a marked broadening of the equivalent line width. Apparently, this can be attributed to a spatial variation in magnetic field in the source. Such an interpretation also holds for many other bursts, for example, those with the spectra shown in Fig. 1d–f. Here the absorption line spreads into a band because of a substantial change in magnetic field within the source.

Figure 2a, b shows spectra with absorption lines obtained for the bursts on 29 March 1979 and 24 May 1979. Note that these bursts were recorded by the Venera 11 detector whose energy

Fig. 2 The energy spectra of γ -bursts. a, 29 March 1979 (1, the spectrum of the initial stage of the burst; 2, the spectrum obtained for the deep minimum between the burst peaks); b, 24 May 1979; c, 31 July 1979 (initial stage); d, 6 October 1979 (initial stage); e, 26 May 1979; f, 22 June 1979.

Fig. 3 The energy spectra of γ -bursts with emission lines. *a*, 5 March 1979 (the spectrum of the short initial pulse); *b*, 18 September 1978; *c*, 18 April 1979; *d*, 16 January 1979; *e*, 4 November 1978 (initial stage); *f*, 19 November 1978 (initial stage).

threshold lies at ~ 17 keV in contrast to the other five detectors with a threshold of ~ 30 keV. This enabled us to obtain additional information. The radiation level in the first, the softest channel of the spectra of these bursts, is higher than normal and remains nearly constant during the burst. The 29 March 1979 event consists of many peaks and lasts about 40 s (ref. 14). The last measured spectrum (2 in Fig. 2a) falls on the deep minimum between the peaks—its shape corresponds to radiation from a substantially colder plasma with temperature $kT \approx 8$ keV. A comparison of the two spectra in Fig. 2a shows that the soft component of the radiation is present during the entire burst. This suggests that the bursts on 29 March 1979 and 24 May 1979 come from two-component sources. It is unclear whether the appearance of the absorption lines can be associated with the presence in the source of a substantially more stationary and colder plasma.

Figure 2c, d shows absorption at the initial stages of the 31 July 1979 and 6 October 1979 bursts which also undergoes evolution, disappearing at later stages. All these graphs demonstrate the similarity between the patterns of absorption in the spectra with substantially different spectral distributions in the continuum.

The burst on 26 May 1979 (Fig. 2e) revealed an emission line at 45 keV. From our data, this spectrum is the only reliable evidence of emission at the cyclotron frequency ω_H . Figure 2f shows a spectrum of the 22 June 1979 burst which is remarkable in that it contains in addition to the cyclotron absorption line and an emission line at 460 keV which is apparently due to the annihilation radiation. The energy of this line was reduced $(1 - 2GM/c^2R)^{1/2}$ times as a result of gravitational redshift in the field of a neutron star.

The same emission lines were also observed in several other γ -ray bursts (Fig. 3). These data show that the relative intensity

of the emission lines, just as that of the absorption lines, can vary in a time shorter than the burst duration. The line emission seems most likely to appear at the burst stages characterized by the highest temperature of radiation in the continuum. Indeed, the line at ~ 430 keV in the burst on 5 March 1979 can be seen only in the hard spectrum of the short initial pulse¹¹. A broad line at ~ 400 keV simultaneous with hard radiation in the continuum can only be observed at the initial stage of the 4 November 1978 burst. The event on 19 November 1978 is distinctive because of its extremely strong evolution of the spectral distribution⁹. The very hard spectrum with a broad emission feature at 300–800 keV (Fig. 3f) is observed during the first 4 s of the burst. The resolution in this region of two lines at 420 and 740 keV (ref. 12) apparently represents the only case of observation in a γ -ray burst of a line above 500 keV. The temporal evolution of the emission lines in the 18 September 1978, 18 April 1979, and 16 January 1979 bursts is less pronounced.

Tables 1 and 2 contain data on lines in the γ -ray bursts, showing the date of the event, the time of the beginning of recording T_0 , and the energy flux S (>30 keV) integrated over the burst duration. For the emission lines the mean energy $\bar{E}$, the mean photon flux F , the energy flux S_e emitted in the line, and the ratio S_e/S are given. The parameters for the absorption lines are the mean energy $\bar{E}$, the relative line depth h in units of the continuum intensity, the estimated equivalent line width $W = \int h dE$, the estimated fraction of absorbed energy flux in the burst S_a , and the ratio S_a/S . If evolution of a line was observed, the values of S and S_e/S , or S_a/S calculated for the burst stage with the line are also given in brackets.

The figures and tables show that the lines in different bursts have fairly similar characteristics. Emission lines appear predominantly in the interval 400–460 keV and the energy

contained in these constitute 5–10% of the energy of the burst. Absorption lines are observed in the 30–70-keV region and the equivalent line widths constitute 5–15 keV, thus 1–2% of the energy of the burst is absorbed. In some cases the lines become smeared strongly and the integral absorption in the soft region of the spectrum increases. The temporal evolution of lines in different bursts also reveals common features. Such a similarity supports our interpretation of the spectral features in the γ -burst spectra as cyclotron absorption lines and redshifted annihilation lines. Thus an overall analysis of our data leads to a conclusion that γ -bursts are produced in regions with a gravitational potential of $\sim(0.1\text{--}0.2)c^2$ and magnetic field $\sim(2\text{--}6) \times 10^{12}$ Oe near the surface of neutron stars. Strong support for these neutron stars being actual components of binaries¹⁶ is the discovery of a similar cyclotron absorption line at 20 keV in the spectrum of the pulsed hard X-ray flux¹⁷ from 4U0115+63.

Observations of a circumstellar shell around the OH/IR star OH127.8–0.0

R. S. Booth, A. J. Kus*, R. P. Norris & N. D. Porter

University of Manchester, Nuffield Radio Astronomy Laboratories, Jodrell Bank, Macclesfield, Cheshire SK11 9DL, UK

The 1,612 MHz OH maser emission associated with cool long-period variable stars is generally characterized by two main regions of emission separated in velocity by $\sim 10\text{--}50$ km s^{−1}. This has been taken to indicate that the OH lies in an expanding shell surrounding the star, the main peaks originating at the near or far sides of the shell along the line of sight where the maser column lengths may be greatest. Here we present the first high-angular resolution measurements of the OH emission from such a source which demonstrates dramatically that this picture is correct.

The 1,612-MHz OH maser source, OH127.8–0.0 (hereinafter called OH127.8) was discovered in a survey by Bowers¹. Like many other sources found in such surveys^{2,3}, it shows the OH characteristics of the long period variable stars but has no optical identification although it is probably coincident with an IR star⁴. These objects have been designated Type II OH/IR stars and are assumed to be long period variable stars which are either at too large a distance for optical identifications or have circumstellar shells which are too thick for the visible radiation to penetrate (their properties are discussed elsewhere^{5,6}).

Observations of the OH maser radiation from OH127.8 were made between late 1978 and early 1980 with three single baseline interferometers of the Jodrell Bank telescope network, before the completion of the new Multi Telescope Radio Linked

Fig. 1 The 1,612 MHz OH spectrum of OH127.8. The bracketed velocity intervals *a*, *b*, *c* and *d* represent those ranges of velocity for which the spatial distribution of the maser emission has been determined (see Fig. 2).

Interferometer (MTRLI)⁷ and as a prelude to its use as a line instrument.

These observations of OH maser radiation form part of a larger programme of observations of several such objects using the MkIA–Knockin, the MkIA–Defford and the MkIA–MkIII interferometers respectively⁸. On each occasion the usual radio link technique was used and the data were cross-correlated in the 1,024-channel digital spectrometer to give a 512 point cross-correlation spectrum in the manner described by Norris and Booth¹⁸.

The autocorrelation spectrum of OH127.8 is shown in Fig. 1. The special feature of this source is that the narrow spectral component at -65.7 km s^{−1} was virtually unresolved on all baselines and could therefore be used as phase reference not only to correct the phase on all the other channels of the cross-correlation spectrum but also to combine the three sets of interferometer data. After combination and normalization the new data set was split into velocity intervals and a series of maps produced, each corresponding to a particular range of velocities in the masing gas. The procedure, described fully elsewhere⁹ consisted essentially of Fourier inversion and cleaning⁹.

Four of the maps are reproduced in Fig. 2*a–d*—they represent the spatial distribution of the masing gas in the velocity intervals *a*, *b*, *c* and *d* indicated in Fig. 1. Figure 2*a* is a map of the distribution of the OH gas with velocities close to the reference feature and in the range -65 to -66.5 km s^{−1} (region *a* in Fig. 1). It shows that the material within this velocity interval is concentrated in a small region of angular extent ~ 0.4 arc s and is

Fig. 2 *a–d*, Maps of the spatial distribution of the integrated OH emission in the velocity intervals marked *a* to *d* respectively in Fig. 1. In each map the contour interval is 5% of the peak integrated emission in that velocity interval and the lowest contour is $\sim 10\%$.

* Permanent address: Nicolaus Copernicus University, Gagarina 11, 87-100 Toruń, Poland.

dominated by the -65.7 km s^{-1} component. Figure 2d shows the distribution of OH in the corresponding redshifted velocity interval (-43 to -43.7 km s^{-1}) and is clearly similar in extent although slightly offset in position.

Figure 2b, c shows maps of the weaker OH emission in velocity regions closer to the stellar velocity (-62.2 to -64.7 km s^{-1} and -45.2 to -47.5 km s^{-1} respectively). Both have a similar annular form with angular diameter $\sim 2 \text{ arc s}$. The map centres are the same in each case and correspond to the position of the reference feature.

The distributions found are exactly those expected of a uniformly expanding circumstellar shell¹⁰ of OH. The strongest

maser components have small angular diameters and are situated close to the line of sight through the centre of the shell along which the gain paths are largest, and the weaker emission delineates those portions of the shell where constant velocity path lengths along the line of sight will be shorter, giving lower maser gain. At the edges of the shell the velocity gradient is such that the line of sight emission is reduced to zero.

Note that the spectrum of the source varied slightly in intensity between observations thus we could not be sure of the relative amplitudes to better than 10%. However, as the fits to the data were good, we believe that our normalization was correct; as an example, in Fig. 3 we show a plot of the data and

Fig. 3 A plot of the visibility phase (ϕ) and amplitude (A) of the OH emission in the velocity range b of Fig. 1 together with the same data (solid line) derived from Fourier inversion of the map plotted in Fig. 2b. Baselines, *a*, MkIA-MkII; *b*, MkIA-Knockin; *c*, MkIA-Deffprd.

corresponding points produced by Fourier inverting the map of Fig. 2b. As an extra check on this effect, we varied the amplitudes by 10% on each baseline and repeated the fitting procedures. In all cases, although the detailed distribution changed, the overall shell pattern remained, it being strongly dependent on the phase data which were always referenced to the unresolved point component at -65.7 km s^{-1} .

Assuming the uniformly expanding shell model¹⁰, the radius at which the line of sight component of the expansion velocity is v , $a(v)$ is given by

$$a(v) = R[1 - (v/v_e)^2]^{1/2}$$

where v_e is the expansion velocity and R the total shell radius. In the case of OH127.8, the expansion velocity (half the interval between OH peaks in Fig. 1) is $\sim 11 \text{ km s}^{-1}$. The rings of emission in Fig. 2b, c have mean velocity relative to the star of 8.5 km s^{-1} and angular diameter ~ 2 arcs. Thus the total shell angular diameter is ~ 3.1 arcs which corresponds to a linear diameter of $1.5 \times 10^{17} \text{ cm}$ if we take the kinematic distance to the star to be 3.3 kpc^{11} .

A technique used recently to determine the linear diameter of the OH shells surrounding long period variable stars¹² involves careful observation of the OH variability when a phase difference can be observed in the light curve of the blueshifted emission from the nearside of the shell, relative to the redshifted emission from the far side. Assuming that the central star is the source of pump radiation, the OH emission from the entire shell should vary in unison and the observed phase lag represents the shell crossing time. Phase lag measurements by Jewell *et al.*¹³ and Herman and Habing¹⁴ show that diameters, d , lie in the range $10^{16} \text{ cm} < d < 10^{18} \text{ cm}$. Although these groups have not sufficiently monitored OH127.8 to obtain a definite phase lag result on this source, our value of diameter lies well within the range of measured values.

The mass of the circumstellar shell and particularly the mass loss rate from long period variable stars are of great importance in understanding stellar evolution and the chemical composition of the interstellar gas. Observations of the circumstellar masers will provide information on the masses involved if the gas density in the shell can be determined. This involves a determination of the OH column density through consideration of the brightness temperature of the maser, its degree of saturation and the efficiency of its pump mechanism, and an estimate of the abundance of OH relative to H_2 . In the case of OH127.8, individual maser features are unresolved with our longest baseline and they may be as small as 30 m arc s (ref. 11). Thus their brightness temperatures are $\sim 10^9 \text{ K}$. An efficient $35\text{-}\mu\text{m}$ IR pumping scheme for the masers in circumstellar envelopes has been developed by Elizur *et al.*¹⁵ and their calculations show that the $1,612 \text{ MHz}$ transition is inverted and saturated for OH densities $n_{\text{OH}} \geq 1 \text{ cm}^{-3}$. Brightness temperatures of $\sim 10^9$ are produced for OH column densities $\sim 10^{17} \text{ cm}^{-2}$, which agrees with our observations. A detailed model of the circumstellar OH abundance has been developed by Goldreich and Scoville¹⁶ who argue that $n_{\text{OH}} \geq 1 \text{ cm}^{-3}$, at a radius of $\sim 10^{16} \text{ cm}$ when the molecular hydrogen number density is $\sim 2 \times 10^4 \text{ cm}^{-3}$. This value, together with our measured linear diameter, gives a value of $\sim 10^{-1} M_{\odot}$ for the mass of the shell and a mass loss rate $\sim 8 \times 10^{-5} M_{\odot} \text{ yr}^{-1}$. Although such a mass loss rate is extremely high, it agrees well with rates derived for a sample of OH/IR stars from measurements of their IR properties, luminosity and dust shell opacities together with the outflow velocities¹⁷. Clearly, stars losing mass at these rates must be short-lived phenomena.

Finally OH/IR stars generally have angular sizes which lie in the resolution range of the MTRLI and observations are already being made using this instrument. As well as measuring the detailed structure and mass loss rates of these fascinating objects, a combination of the angular size of their shells from interferometry and the direct (phase lag) measurement of their diameter will lead to valuable independent estimates of their distances.

We acknowledge the assistance of Dr B. Anderson with some of the equipment and Drs P. N. Wilkinson, R. G. Noble and T. J. Cornwell for their advice on the mapping procedures. A.J.K. received a British Council support grant.

Fragmentation of a meteor in near-Earth space

M. A. Hapgood & P. Rothwell

Department of Physics, The University,
Southampton SO9 5NH, UK

Fragments of a Perseid meteor, which broke up well above the Earth's atmosphere, probably in collision with a dust particle in near Earth space, have been observed with a two-station low-light level television camera system. Three Perseid meteoroids, with apparent magnitudes between 2.0 and 3.5, arrived on near parallel trajectories within 1.3 s of each other on the morning of 12 August 1977 (03.05.21–03.05.23 UT). The probability of these meteoroids arriving by chance so close together in time and direction is very small ($\sim 3 \times 10^{-11}$). Assuming the three meteoroids were fragments of a larger body, we show here that the parent meteor must have broken up at least 1,700 km above the Earth's surface, well above the altitude at which meteoroids normally start to burn up in the Earth's upper atmosphere (100–150 km). An estimate of the size of the parent meteor has been made from the observed magnitudes of these fragments. Assuming the parent meteoroid was spinning with an angular velocity between 100 and 1,000 rad s^{-1} , an upper limit to the distance of breakup point from the Earth's surface can be placed at between 7×10^5 and $7 \times 10^6 \text{ km}$ (0.004–0.04 AU). We show here that the probabilities of collision and breakup of the parent Perseid with three classes of dust particle in near Earth space—interplanetary, magnetospheric and lunar ejecta—at the time of our observation in 1977, were $\sim 3 \times 10^{-6}$, 3×10^{-6} and 5×10^{-7} respectively. We suggest therefore that if the Perseid parent comet (Swift–Tuttle) passes close to the Earth when it returns to perihelion in the next year or two, giving rise to a spectacular display of the Perseids, we should then be able to see many of these associated meteor events, and to study meteor collision with dust particles in near Earth space.

Table 1 Meteor parameters

	Meteor 1	Meteor 2	Meteor 3
Geocentric radiant:			
RA (α)	3 h 26 min	3 h 31 min	3 h 19 min
Dec (δ)	+53.7°	+54.2°	+53.8°
Geocentric velocity (km s^{-1})	59 $\pm$ 2	59 $\pm$ 2	56 $\pm$ 3
Apparent magnitude	2.0 $\pm$ 0.5	2.1 $\pm$ 0.5	3.5 $\pm$ 0.5
Magnitude at zenith	0.5	0.6	1.8
Mass (10^{-5} kg)	13	12	4

The meteor observations were made with low-light level TV cameras and associated video recording equipment at two sites in the south of England; Southampton (50°50' N, 1°24' W) and Harwell (51°35' N, 1°20' W). An image isocon camera, with a 30° × 23° field of view, was used at Southampton and a silicon intensified target (SIT) camera, with a 20° × 15° field of view, was used at Harwell. Both cameras looked west at a common volume centred above South Wales at a height of ~100 km. Fifty pictures per second were recorded on video tape; these pictures could be played back slowly frame by frame. Typically a meteor appeared in ~10 successive frames.

The positions in space of the three associated Perseids were determined by triangulation against the fixed star background using observations from the two sites. Figure 1 shows the variation of the altitude of the lower tip of the meteor trails with time; Fig. 2 shows the positions of the three trails projected onto the ground. The velocities and radiant of the three meteors are listed in Table 1; they all lie close to the mean Perseid values¹ (geocentric velocity 59.4 km s⁻¹, geocentric radiant $\alpha = 3$ h 05 min, $\delta = 57.4^\circ$). The error in the determination of each velocity is ~2 km s⁻¹; the error in the position of one radiant relative to another is ~1°. The apparent magnitude of each meteor was determined by comparing its brightness with the brightness of stars in the field of view. The meteor magnitudes, corrected to the zenith², are also listed in Table 1, together with the masses, estimated from the zenith magnitudes, following Hughes³.

The three meteors arrived within a time interval of 1.3 s and on trajectories which were parallel to within 1°, that is, within a solid angle of ~10⁻³ sr. In contrast the average meteor rate in the field of view of our cameras during the Perseid meteor shower was ~6 h⁻¹; the radiant of these meteors were spread over a wide region of the sky ~12° across (solid angle ~0.15 sr). Thus the probability of observing by chance three meteors arriving so close together in time and direction was ~3 × 10⁻¹¹.

By combining the masses of the three meteors (see Table 1) we can estimate that the mass of the parent body was ~3 × 10⁻⁴ kg. If we assume that the parent body was roughly spherical and had a typical Perseid density⁴ of 290 kg m⁻³ its radius was ~6 mm.

We can estimate the distance s from the Earth back to the breakup point since $s = v^2 \Delta t / \Delta v$, where v is the mean velocity of the fragments, Δv is their velocity dispersion and Δt is the time interval between the arrival of the fragments. The mean velocity ($v = 58.5 \pm 1.3$ km s⁻¹) and the time interval ($\Delta t = 1.30 \pm 0.02$ s, see Fig. 1) are known quite accurately. However, the velocity dispersion Δv lies within the errors of measurement so the error in the mean velocity sets an upper limit on Δv . We take $\Delta v_{\max}$ to be 2.6 km s⁻¹, which gives a value of the minimum distance to breakup point, $s_{\min}$ of 1,710 km. We can make a second and independent estimate of $s_{\min}$ from the observation that the

Fig. 1 The variation of meteor heights as a function of time.

Fig. 2 The horizontal motion of the meteors. The position of each meteor is shown at time intervals of 20 ms (1 TV picture). The inset shows the area (shaded) of the main map and the positions of the two observing sites: Southampton (S) and Harwell (H).

meteor fragments travelled on paths which were parallel to within the errors of measurement (1°) and were ~30 km apart at 105-km altitude. Taking the maximum angle of dispersion between the trajectories to be 1° we obtain $s_{\min} = 1,720$ km which agrees well with the value deduced from the velocity dispersion. This puts the fragmentation point outside the Earth's atmosphere, thus a high velocity collision between the parent body and a small dust particle would be the likely cause of fragmentation.

We can set an upper limit to the distance of the breakup point from the Earth if we can set a minimum value for the velocity dispersion of the fragments ($\Delta v_{\min}$). In general we would expect a significant velocity dispersion to be generated by the collision. However, in the case of a collision with a small dust particle which is only just large enough to cause fragmentation, almost all the kinetic energy of the collision would be dissipated in breaking up the parent meteoroid. In such cases the only contribution to the velocity dispersion is that arising from the rotation of the parent body. Thus we may put $\Delta v_{\min} \sim \omega r$ where ω is the angular velocity of the parent body and r is its radius. Theoretical studies indicate that meteoroid spin may be produced by collisions⁵ and by solar radiation effects⁶. These theories indicate that angular velocities of 100–1,000 rad s⁻¹ may be achieved within the lifetime of the Perseid stream (~3,000 yr (ref. 7)). This implies a value for $\Delta v_{\min}$ in the range 0.6–6 m s⁻¹ giving a value $s_{\max}$ in the range 7–70 × 10⁵ km (0.004–0.04 AU). Thus we may conclude that the parent body broke up in space close to the Earth.

The minimum mass of dust particle needed to fragment the parent body can be estimated from the results of the hyper-velocity impact experiments of Moore and Gault⁸. They found that a body of mass M would be fragmented by the impact of a particle of mass m and relative velocity v km s⁻¹ when $m > M/250 v^2$. If we apply this formula to the present case we find that a dust particle of minimum mass 3×10^{-10} kg would be required to give fragmentation. However, note that the hyper-velocity impact experiments from which the formula was derived were carried out on basalt targets with relative velocities up to 7 km s⁻¹. The use of the Moore and Gault⁸ formula involves considerable extrapolation in velocity and assumes that the meteoroid material fragments in similar conditions to basalt.

We may estimate the probability of observing a group of associated meteors by calculating the probability of the parent body suffering a collision. Dohnanyi⁹ has calculated the collisional lifetimes T_c of meteoroids in several meteor streams, with interplanetary dust particles, taking into account both the meteoroid cross-section and the number density of dust particles which are, according to Moore and Gault⁸, large enough to cause fragmentation. He finds that, for the Perseids, $T_c = 1.8 \times 10^4 M^{1/3}$ yr where M is the meteoroid mass in kg. Thus

with $M = 3 \times 10^{-4}$ kg, $T_c = 1,200$ yr (4×10^{10} s). The probability of collision with an interplanetary dust particle within 7×10^6 km of the Earth, for a meteor of mass 3×10^{-4} kg travelling at 58.5 km s $^{-1}$, is $\sim 3 \times 10^{-6}$. This is a small probability but still $\sim 10^5$ times higher than the chance probability of three meteors arriving so close together in time and direction.

Fechtig *et al.*¹⁰ have reported that the flux of dust particles in the mass range 10^{-12} – 10^{-18} kg observed from the HEOS 2 satellite within the Earth's magnetosphere, is ~ 100 times greater than the flux in interplanetary space. If a similar enhancement exists for masses of $\sim 10^{-10}$ kg, the collisional lifetime for a Perseid in this region would be reduced to $\sim 4 \times 10^8$ s. It takes $\sim 1,000$ s for a Perseid to cross the magnetosphere, thus the probability of a catastrophic collision with a magnetospheric dust particle is therefore $\sim 3 \times 10^{-6}$, which is comparable with the probability of a collision with a dust particle in interplanetary space.

Fechtig *et al.*¹⁰ also observed groups of particles from the HEOS 2 satellite which are believed to be high velocity ejecta from the impact of large meteoroids on the surface of the Moon. The flux of these particles was about one-tenth of the flux of dust particles in interplanetary space. During meteor showers the number of lunar ejecta increases. Alexander and Corbin¹¹ have calculated that the mass flux ejected from the lunar surface by the Perseid meteor shower is ~ 30 times that ejected by sporadic meteors. They have also shown that when the Moon is in the last quarter, a large percentage of the lunar ejecta are directed towards the Earth. At the time of our observation of 12 August 1977, the lunar phase angle from full Moon was 146° (in the last quarter). The flux of lunar ejecta near the Earth may, therefore, have been about three times the interplanetary dust flux. If these ejecta particles are concentrated in a region comparable in size to the Moon's orbit (4×10^5 km) then the probability of a catastrophic collision with a lunar ejecta particle is $\sim 5 \times 10^{-7}$.

The three Perseid meteors we observed ablating in the Earth's atmosphere, closely associated in space and time, are likely to be fragments of a larger Perseid meteoroid of mass 3×10^{-4} kg which broke up between $1,700$ and 7×10^6 km from the Earth's surface. The probability P_1 that they are fragments from a single meteor colliding with a dust particle in interplanetary space is $\sim 10^5$ times greater than the probability of a random association between the three meteors. The probability P_2 that the parent Perseid collided with a dust particle in the higher density dust environment of the Earth's magnetosphere is comparable with P_1 . The probability P_3 that the parent Perseid collided with a moon dust particle ejected when the Moon was bombarded with meteors from the Perseid shower, is $\sim$ one-sixth of P_1 .

If the Perseid broke up on collision with a dust particle we were lucky to observe this event. The chance of an individual meteor breaking up close to the Earth was of the order of a few in a million and we recorded less than 100 meteors during the 1977 Perseid meteor shower. During spectacular displays of meteors, when the parent comet passes close to the Earth, the meteor rate can rise by two or three orders of magnitude. The dust population in the magnetosphere and the density of lunar ejecta in near Earth space should rise and the chance of an individual meteoroid breaking up close to Earth on collision with a dust particle could increase up to a few in a thousand. In this case several events of the type we have described could be observed during the meteor display. The parent comet of the Perseid meteor stream (Swift–Tuttle, 1862 III) is expected to return to perihelion sometime in the next year or two. There has been speculation that the passage of the comet may give rise to a spectacular Perseid display. We may then be able to make further studies on the breakup of Perseid meteors in near Earth space.

We thank Dr O. Royrvik for observational assistance and Dr J. V. Jelley for use of his observing site at Harwell.

Atomic motion on the surface of a cadmium telluride single crystal

R. Sinclair, T. Yamashita & F. A. Ponce

Department of Materials Science and Engineering, Stanford University, Stanford, California 94305, USA

Cadmium telluride (CdTe) is an interesting semiconductor compound whose photoelectronic properties make it suitable for solar cell applications. We report here a study of defects in CdTe, carried out by lattice resolution imaging in a transmission electron microscope (TEM), during which observations were made of the motion of image spots at the edge of a specimen. As the spots are related to the projected atomic positions in the structure, this behaviour indicates atomic motion at the CdTe surface. Individual spot jumps occurred several times per second and one could watch the formation and decay of small crystalline facets. The possibility thus arises for surface studies, at the atomic level, in conjunction with direct crystal lattice imaging, allowing investigation of the interaction between surface atoms and their substrate.

CdTe has the zinc blende structure which is best imaged by high-resolution TEM with a $\langle 110 \rangle$ direction parallel to the electron beam. The projection of the structure in this orientation is shown in Fig. 1a. Adjacent columns of cadmium and tellurium atoms are separated by 1.6 Å, but their resolution is only achieved in very restrictive experimental circumstances^{1,2}. More commonly, bright spots are seen in the image (for example, Fig. 1b), the distribution of which corresponds to the arrangement of the projected lattice points. Such images are consistent with comparable images of elemental germanium and silicon which have the related diamond cubic structure^{3–5}. Theoretical image calculations, discussed later, establish the relationship between image spots and the crystal structure.

Microscopy was performed using a Philips EM400 TEM equipped with a high-magnification objective lens ($C_o = 1.1$ mm at 120 kV) and a LaB₆ electron source. This lens has no tilting capability. Therefore the single crystals were sectioned as closely as possible to the desired orientation. Thin foils were obtained by standard ion-milling procedures. A region of the specimen close to the perfect 110 zone axis orientation was found by translating the specimen in the microscope. The present images were taken by allowing 36 beams through the objective aperture (Fig. 1c) although the observations have been repeated with seven beam images. The magnification was $\times 800,000$, with typical exposure times of about 1 s.

In these experimental conditions, it was found that after an initial incubation period the single-crystal specimen deteriorated by the nucleation of new, small crystallites, apparently on the surfaces of the parent crystal. The deterioration time varied from one specimen to another and was typically several hours. Close examination of the specimen edge revealed that individual bright spots were moving about by a random jump process. Jumps occurred several times per second, usually by a distance equal to the atomic column separation. Not all edge spots were moving simultaneously; rather one or two would be moving back and forth along a crystal facet. Unfortunately the time both for transporting photographic

plates into position and for exposing the film was too long to allow the motion of an individual spot to be studied extensively. The jump rate could not be reduced to an acceptable level, for instance through decreasing the incident electron beam current density by defocusing the microscope condenser lens.

The motion of the surface spots is demonstrated here by the appearance of the specimen after intervals of several minutes. Thus it can be seen in Fig. 2 that the shape changes noticeably with time, although the crystal structure of the interior is always maintained. The general impression was that small facets were produced, the longer ones being parallel to {111}-type planes. The bright spots at the edge move from one lattice site to another. When they become incorporated into the crystal, they extend it and the image is indistinguishable from the perfect crystal image. These observations, therefore, seem to indicate that atomic motion is occurring along the edge of the specimen, and probably across all surfaces. Those atoms which move on

the surface normal to the electron beam will coincide exactly with the underlying atomic columns if tetrahedral coordination is to be maintained. Therefore one would not detect directly motion of these latter atoms.

To interpret the image-spot motion the relationship between the image and the CdTe crystal structure must be understood. As the image comprises bright spots, the specimen must have finite thickness. Image calculations¹ indicate that the thickness is probably in the range 40–100 Å. Furthermore, to detect a bright image spot an atomic column of at least several unit cells is necessary. Thus the spots at the specimen edge do not arise from single atoms nor from single CdTe molecules but rather from a significant column of atoms probably of dimension similar to that of the adjacent bulk crystal. The movement of spots represents coordinated motion of a whole or partial atomic column but not the jumping of single atoms. For the observation to be made, the number of atoms that move must be sufficient to produce a detectable image spot. In the present case this is thought to be a column of about five atoms (~20 Å long).

The image spots may coincide with three positions in the projected structure depending on the particular combination of the experimental variables of microscope defocus, spherical aberration coefficient and specimen thickness¹. These positions are at the open channels in the structure, at the position of one species or at the midway point between the closest Cd–Te atomic columns. (Only the first and last occur in images of Ge and Si⁶.) However, the image spot motion is independent of its exact position. Thus the jump of the Cd–Te molecule 'A' in Fig. 3 would be seen as a spot moving whether the spot coincides with the molecule, one atom, or the adjacent column. The argument also holds for other possible migration mechanisms indicated in Fig. 3. Distinction of the various mechanisms would require quantitative measurements of the intensity of particular image spots, at known focus settings, including careful image recording by a television system.

The driving force for the present behaviour is presumably reduction in total surface area. Using a simple formulation for atomic jump frequency ($\nu_0 \exp -Q/kT$), it is found either that the activation energy (Q) for the present observations is 0.8 eV if they occur at room temperature, or that the specimen temperature is ~110 °C if the activation energy is assumed to be the sublimation energy of CdTe (1.03 eV)⁷. The latter is thought to represent the present situation. Thus, the observations are only made after the specimen temperature rises sufficiently due to heating by the incident electron beam. As exposure continues, the motion becomes more rapid with more drastic specimen deterioration. Variation between specimens arises from their exact geometry and from the degree of contact between the specimens and a supporting metal grid. Complete isolation of the CdTe is found to result in extremely rapid specimen destruction. The slow response of the jump rate on reducing the beam current density indicates that the atomic motion is not assisted by direct electron–atom collisions (the electron energy is well below the threshold for Cd or Te displacement) or by ionization effects, and probably arises from a sluggish heat dissipation from the active area. A more sophisticated analysis would need to take into account the mechanism of coordinated atomic column motion.

Whether these results are confined to CdTe or represent a more general phenomenon, previously undetected, remains to be seen. Certainly the absence of a specimen contamination film in the present work is a factor contributing to the observations. CdTe has the lowest sublimation energy of the common semiconducting materials⁷. If the present ideas are correct then equivalent observations may be made on other similar solids if higher temperatures are achieved. For example, jump frequencies several times per second would be expected at 600 °C for silicon ($Q = 2.32$ eV), 340 °C for gallium arsenide ($Q = 1.63$ eV) and 260 °C for cadmium sulphide ($Q = 1.42$ eV)⁷. *In situ* specimen heating, together with lattice resolution, would be necessary to detect these phenomena which should soon be possible on commercial TEMs.

Fig. 2 Series of structure images of the same region near the specimen edge taken several minutes apart. The stacking fault (arrowed in *b*) can be used as a reference mark for each photograph. The specimen shape and its spot distribution change noticeably with time.

Direct investigations of atomic motion by electron microscopy have previously only been made without imaging the substrate. Scanning transmission microscopy results of heavy-metal atoms on amorphous carbon^{8,9} are well known, with complementary reports using fixed-beam TEM by dark field¹⁰ or bright-field imaging of atoms on graphite¹¹. Field-ion microscopy allows the imaging of both surface and substrate^{12,13} albeit of limited areas on a restricted number of materials. The present observations are thought to be the first using fixed-beam TEM, combining direct imaging of the moving species with the crystal structure of the parent material. However, unlike these other studies, they represent motion of a small group of atoms, by an undetermined mechanism, rather than of single atomic jumps.

The observations reported here have been interpreted as representing the migration of atomic columns (comprising at least five atoms and probably more) due to thermal activation induced by beam heating. A more detailed description of the

mechanism of this behaviour requires more rapid recording (for example, at television rate), extensive image calculations relating spot brightness to column thickness and a more extensive theoretical model of coordinated atomic jumps. Although this work is preliminary it has important implications. Thus with careful experimentation it should be possible to study directly self-migration on CdTe and determine the associated atomic mechanisms. If, as we suspect, the observations are not confined to CdTe, then atomic motion studies on this important class of materials are feasible. Finally, other surface-related phenomena may also be investigated, for example, the action of foreign species (such as metal atoms) and the influence of crystallography and crystal defects on the atomic behaviour. Such experiments would provide important information for understanding how the surfaces of such solids may influence their properties and their technological applications.

High-voltage, high-resolution lattice images of dolomite

D. J. Barber

Physics Department, University of Essex, Colchester CO4 3SQ, UK

L. A. Freeman & David J. Smith

High Resolution Electron Microscope, University of Cambridge, Cambridge CB2 2QH, UK

Dolomite, $\text{CaMg}(\text{CO}_3)_2$, which belongs to the rhombohedral group of carbonates, is an important mineral commonly found in sedimentary and metamorphic environments. Ideally, it has an ordered trigonal structure ($R\bar{3}$) with planes containing atoms of only Ca, or only Mg, alternating and being interleaved with the planes containing the carbonate groups. All these planes are perpendicular to the 3-fold axis. As the microstructural deformation observed in many natural dolomites of low and medium metamorphic grade could provide an insight into the geological history, attention has recently been directed to electron microscope studies¹⁻⁴ of the mineral. Unfortunately, at a typical accelerating voltage of 100 kV, dolomite is highly susceptible to damage by the electron beam, whereas, at a voltage of 1 MV, little electron damage is noticeable¹. We report here observations of dolomite with the Cambridge University 600-kV high-resolution electron microscope^{5,6}. Although electron beam damage is still observed at the intermediate operating voltages of this microscope, it has been possible, with care, to resolve directly details of crystal lattices in two dimensions. Thus, direct confirmation has been obtained of postulated models for the common types of stacking faults observed in dolomite.

Much of the recent interest in dolomite stems from three observations:

(1) Single crystals of stoichiometric dolomite exhibit an unusual increase in mechanical strength with temperature up to $\sim 800^\circ\text{C}$ (refs 7, 2, 4), which seems to be a consequence of the detailed atomic displacements accompanying dislocation motion through the ordered structure.

(2) Attempts to synthesize dolomite in conditions similar to those in which sedimentary dolomites seem to have formed have failed^{8,9}. Moreover, although the ordered phase is more stable than disordered dolomite, the latter can exist for geologically long times. 'Geologically young' dolomites are mostly imperfectly ordered and calcium rich; embryonic analogues of the abundant, more perfect dolomites found in old environments have not been discovered.

(3) Recent work has shown that local disorder can be produced in near-perfect single crystal dolomite by slip on the (0001)^{2,4} and $\{01\bar{1}2\}$ planes⁴. X-ray structure refinements on Eugui dolomite which was thermally disordered and then quenched in a laboratory experiment indicate¹⁰, however, that other forms of disorder also occur in which some of the carbonate groups (which should ideally be oriented at 180° about the 3-fold axis with respect to the groups in adjacent carbonate planes) are misoriented by 180° . In addition, electron microscopy of non-stoichiometric sedimentary dolomites¹¹ has shown the existence of a new type of superstructure which effectively doubles the length of the a axis.

All these observations indicate the value of gaining direct information about types of disorder in dolomite. An obvious approach would involve lattice imaging techniques with a high-resolution electron microscope although, as mentioned above, dolomite is considerably electron sensitive because of local heating and ionization damage caused by the electron beam. Indeed, previous efforts at 100 kV have barely resolved the 0.54-nm (0003) lattice fringes in one-dimension only¹⁰. However, results have been improved by raising the beam

energy, which effects an appreciable decrease in the sensitivity of dolomite to beam damage, and by applying a variation of the so-called 'minimal exposure technique'¹² whereby tilting of the dolomite crystal to the required orientation is done using a focused beam of very low intensity on a small area of crystal. After focusing and correction of astigmatism, images are recorded of crystal defects and other interesting morphological features in nearby areas, previously unexposed to the intense electron beam. Local bending of the crystal lattice sometimes occurred but accurate alignment of the crystal normal and the zone axis projection was generally retained so that two-dimensional crystal structure images could be obtained.

The two-dimensional lattice image in Fig. 1 shows stacking faults produced by slip on the $\{\bar{1}012\}$ planes in a single crystal of a stoichiometric and fairly pure dolomite (Eugui) which was experimentally deformed at 20°C under a confining pressure of 0.7 GPa. The electron beam is exactly parallel to a $\langle 10\bar{1}1 \rangle$ zone axis, as indicated by the selected area diffraction pattern. Two sets of $\{\bar{1}101\}$ and one set of $\{\bar{1}012\}$ lattice planes are resolved, with spacings of 0.40 and 0.37 nm respectively.

Figure 2a shows the structure image of a thin crystal of the same Eugui dolomite which was experimentally deformed at 420°C under confining pressure in an orientation which promoted slip on the (0001) planes. In this case the electron beam is exactly parallel to a $\langle 11\bar{2}0 \rangle$ direction. $\{\bar{1}101\}$, $\{\bar{1}012\}$, $\{\bar{1}014\}$ and (0003) planes are parallel to the beam, as can be seen from Fig. 2b, which shows the atomic structure when viewed in this projection. The orientations of the carbonate groups, whose planes are strictly normal to the projection plane, are given by black triangles in this representation. A basal stacking fault, which results from slip on the (0001) $\langle 1\bar{2}10 \rangle$ macroscopic system, appears in Fig. 2a. The fault is apparently bounded by $1/3[1100]$ partial dislocations, as previously deduced from diffraction contrast experiments¹³, but it is broader in the (0001)

Fig. 1 Lattice image from a moderately thick crystal of dolomite in a $\langle 10\bar{1}1 \rangle$ projection showing a series of deformation-induced planar stacking faults on the $\{\bar{1}012\}$ planes, together with the corresponding electron diffraction pattern (inset). The lattice planes imaged are $\{\bar{1}011\}$, $\{\bar{1}012\}$ and $\{01\bar{1}1\}$; the faults do not produce apparent offsets of these planes.

Fig. 2 *a*, Structure image of a thin crystal of dolomite taken in a $\{11\bar{2}0\}$ projection; the 0.534-nm (0003) basal plane spacing is indicated. A deformation-induced basal stacking fault is visible. Confirmation of postulated models for such stacking faults are directly obtainable. *b*, Representation of a section through a $\{11\bar{2}0\}$ plane of dolomite, showing alternating layers of Ca and Mg atoms, separated by planes of CO_3 groups parallel to the basal planes (0001). The plane of each CO_3 group is actually exactly parallel to (0001) but small (tilted) triangles are used to denote the 180° rotation between groups in adjacent planes.

direction than might be expected from elementary considerations. A more complete analysis and interpretation of (0001) and $\{10\bar{1}2\}$ stacking faults will be presented elsewhere. The disparity in cation sizes is apparent in the structure image of Fig. 2*a*, although, as might be expected, the carbonate groups are not seen in detail.

Clearly, high-voltage, high-resolution electron microscopy is a technique well suited to analysis of order/disorder problems in dolomite. Furthermore, use of this method is expected to add greatly to our knowledge of defect structures in non-stoichiometric and disordered specimens of other carbonates. Sequential images of dolomite which has undergone prolonged electron irradiation have also been obtained, from which it is believed that the nature of the electron damage process will be established. Our preliminary results suggest that the damage propagates along preferred crystallographic directions in common with earlier observations of phthalocyanines¹⁴. This damage ultimately leads to the decomposition of the carbonate to the oxides, as with calcite^{15,16}.

The Cambridge University 600-kV high-resolution electron microscope has been built as a joint project between the Cavendish Laboratory and the Department of Engineering with major financial support from the SRC. We thank the latter for continuing support, R. A. Camps for assistance with preparation of the microscope and H. C. Heard, R. J. Reeder and H. R. Wenk for provision of samples and valuable discussions.

Near-surface turbulence measurements in a lake

T. M. Dillon, J. G. Richman, C. G. Hansen & M. D. Pearson

School of Oceanography, Oregon State University, Corvallis, Oregon 97331, USA

One of the most important but least understood regions of oceans and lakes is the near-surface zone. Exchanges of energy and momentum between the atmosphere and the waters below are controlled by turbulent mixing processes in the surface zone. Major advances in understanding these processes have been hampered by a lack of observations of turbulence near the surface. We have recently constructed a probe which can be used to estimate an important variable in theories of turbulence, the rate at which the kinetic energy of turbulence is dissipated, and have found a surprising though simple result: to a first approximation, scaling laws devised to describe dissipation in the atmospheric boundary layer may also be applicable in the water near the surface.

The probe is a miniaturized version of a high-frequency temperature profiler used previously in upper ocean studies¹. The probe body is a 2.5-cm diameter cylinder, 70-cm long, containing thermistor amplifiers and a pressure transducer. A toroidal buoyancy element 10 cm in diameter and 25-cm long jackets the upper probe body, and a vented drag plate 30-cm in diameter is attached to the rear. The probe is slightly buoyant in water and has a large static stability. A thermistor with a frequency response correctable to 30 Hz is mounted on the nose of the probe. Ballast is attached with a pressure-sensitive release mechanism so that after launching, the probe sinks to a pre-determined depth, releases ballast and rises to the surface at

10 cm s⁻¹. The probe is launched from a small boat, and typically rises 15–20 m away from the launch point, so that water sampled by the probe is unaffected by the boat.

Estimating the dissipation rate from high-frequency temperature measurements depends on finding the wavenumber (inverse length scale) of the smallest appreciable temperature fluctuations^{2,4}. Briefly, the method assumes a competition between the tendency of turbulent stirring to increase temperature gradients and the tendency of molecular diffusion to smooth gradients. The wavenumber at which diffusion can overcome stirring and homogenize the fluid, the Batchelor wavenumber k_B , is a function of the kinetic energy dissipation rate per unit mass, ϵ : $k_B = (\epsilon \nu^{-1} D^{-2})^{1/4}$, where ν is the kinematic viscosity and D the molecular diffusivity for temperature. Wavenumber spectra are calculated from temperature-gradient fluctuations, and by least-squares fitting to the Batchelor spectrum^{2,5,6}, k_B and hence ϵ may be found.

The validity of the method has been tested in the nepheloid layer near the ocean floor. Measurement of the stress on the ocean floor due to near-bottom currents⁷ enables the dependence of the kinetic energy dissipation rate on height above the floor to be predicted. Simultaneous measurement of the temperature microstructure was made and the Batchelor scale method was used to calculate the dissipation rate above the ocean bottom^{8,9}. Comparison of the measurement with the prediction yields excellent agreement⁴.

Measurements were made in Green Peter Reservoir, a small impoundment east of Corvallis, Oregon. The launch site had an unobstructed fetch of 3 km over water, and the depth at anchorage was 50 m. During the experiment, winds averaged 4.8 m s⁻¹. Surface waves averaged 10–20 cm in height, and occasional white-capping was observed. The temperature profile (Fig. 1) displayed an active surface mixing layer to 6 m in depth. A strong seasonal thermocline was at 7 m.

Nine casts were made through the mixing layer, and temperature gradient spectra were computed over 50-cm segments of water. From the surface to 1-m depth, the turbulence was so intense that the frequency response of the thermistor was insufficient to resolve the smallest length scales on half of the segments, and so the dissipation rate could not be reliably resolved; in these cases, we underestimate the dissipation by

Fig. 1 Temperature (right) and temperature gradient (left) profiles for a single cast in the near-surface layer at Green Peter Reservoir, 24 July 1980. Thermocline is at 6-m depth.

Fig. 2 Kinetic energy dissipation rate per unit mass in the near-surface layer (●). Error bars are the standard error of the mean. Solid line is $(\tau/\rho)^{3/2} \kappa^{-1} Z^{-1}$ calculated from mean winds, dotted lines are $(\tau/\rho)^{3/2} \kappa^{-1} Z^{-1}$ calculated from highest and lowest winds. Dissipation falls dramatically in the thermocline at 6 m.

setting it equal to the largest resolvable value. Below the first metre, the dissipation rate decreases, and was resolvable on 90% of the segments. At the base of the layer, the dissipation rapidly falls by an order of magnitude. Averages of the dissipation over the nine casts were calculated in 1-m intervals (Fig. 2).

No detailed theoretical framework for understanding turbulence in a wind driven surface mixed layer has yet received wide acceptance. Attempts at detailed modelling have been made¹⁰ but the complexities of possible interactions of wind, waves, breaking waves and spray, as well as the lack of near-surface observations, have kept most theories of the aquatic mixed layer at a primitive level. In contrast, the theory of the atmospheric boundary layer has been well developed¹¹. It is tempting to ignore the complex nature of the air-sea interaction and apply to the aquatic mixed layer the same framework which holds on the atmospheric side of the boundary. The atmospheric boundary layer prediction in an unstratified flow for variation of dissipation rate with distance Z from the boundary¹¹ is $\epsilon = (\tau/\rho)^{3/2} \kappa^{-1} Z^{-1}$, where κ is the von Karman constant and ρ the water density. Calculating the surface stress during our measurements by the drag law $\tau = \rho_a C_D \bar{U}^2$ (ρ_a is the air density, C_D (ref. 12) is the drag coefficient with value 1.3×10^{-3} , and $\bar{U}$ is the mean wind speed at a height of 5 m), we find remarkably close agreement with the atmospheric boundary-layer prediction. A least-squares fit to the form $\epsilon = AZ^n$ yields $n = -1.03 \pm 0.05$. Within experimental error, the dissipation is inversely proportional to the depth. Testing the magnitude of the dissipation, we find the average value $A = \epsilon Z = 0.51 \pm 0.09 \text{ cm}^3 \text{ s}^{-3}$ which is within experimental error of the independently measured value $(\tau/\rho)^{3/2} \kappa^{-1} = 0.53 \text{ cm}^3 \text{ s}^{-3}$. Exhaustive measurements of ϵ will be required to determine whether or not the atmospheric boundary layer prediction holds to more than a first approximation.

It has been suggested^{13–15} that the near-surface layer may exhibit some of the properties of a constant-stress layer, but the experimental evidence has been too fragmentary to draw firm conclusions. It is premature to suggest that the scaling will hold at all times. At large wind speeds, vigorously breaking surface waves may be an important source of turbulence, and have scaling laws different from the case of small waves and low winds.

Geomagnetic induction on a transatlantic communications cable

L. V. Medford, A. Meloni,* L. J. Lanzerotti & G. P. Gregori†

Bell Laboratories, Murray Hill, New Jersey 07974, USA

The phenomenon of geomagnetically-induced currents in long conductors has been recognized since the mid-nineteenth century, when the use of the telegraph became prevalent in North America and Europe¹. Powering systems of telegraph and telephone cables are now engineered to eliminate large current surges, although the occasional significant geomagnetic disturbance, such as those produced by the February 1958², August 1972³ flare events, can still be a problem. However, induced voltages can be used, with complementary geophysical and geological data, to deduce features of the Earth's crust and upper mantle^{13,14}. Improved scientific understanding of magnetospheric phenomena means that the geomagnetic induction process in long conductors, and thus in the Earth are better understood. For example, the cable outage problem associated with the August 1972 geomagnetic storm interval was qualitatively attributed not to the 'line' currents associated with normal auroral current systems but rather to the significant enhanced currents flowing on the magnetosphere boundary at the time of an extreme compression of this boundary in greatly enhanced solar wind conditions³. We have measured the geomagnetic induction phenomenon on modern-day long cables to get better assessments of the induced currents in various types of geomagnetic variations. Our initial work was concerned with induction in the transatlantic telecommunications cable no. 6 (TAT-6) which is laid between Green Hill, Rhode Island (41.4° N, 71.7° W geographic) and St Hilaire de Riez, France (46.7° N, 1.9° W)⁴. We concentrate quantitatively here on induction by the solar-induced quiet day currents (S_q) in the ionosphere and find that calculated values agree well with observed values of S_q .

The solid line in Fig. 1 shows the approximate route of the TAT-6 cable across the North Atlantic (length 6,300 km). This cable is powered at both Green Hill and St Hilaire by constant current power supplies with opposite polarity at each end producing a current flow from west to east through the cable and repeaters^{5,6}. These repeaters are spaced approximately every 10 km along the route of the cable⁷. The cable is biased at a nominal 5,200 V positive with respect to local ground in North America and 5,200 V negative with respect to local ground at St Hilaire with a maximum capability of 7,500 V from each supply. The present measurements from the Green Hill terminal monitored the geomagnetically-induced currents in the powered

Fig. 1 Approximate location of TAT-6 cable across the North Atlantic (solid line). Model cable path (dashed line).

centre conductor by measuring changes in the conductor to local ground voltage. The voltage drop to ground at St Hilaire was not monitored in these first tests, but will be investigated in future work. To a first order, induction in the cable may be expected to produce equal and opposite voltage changes at the two ends of the system.

The constant current flow (nominal 657 mA) along the centre conductor can be pictured as coming from two sources at each cable end: one being the active power supply and the other the induced voltage produced by the rate of change with time of the geomagnetic field across the cable circuit. Thus, a measure of the time dependence of the externally-induced currents can be obtained by measuring the changes in the output voltage of the constant current power supply. The total d.c. resistance of the centre conductor and repeaters (under power) is ~ 16 k Ω . The time constant of the conductor produced by the distributed cable capacitance and the resistance (end to end) is ~ 10 s. The dashed line in Fig. 1 shows the model cable path that was taken for the modelling of the S_q field in the calculations discussed below.

In addition to monitoring the cable power supply voltage, the Earth's magnetic field in three geomagnetic components (H (north-south), D (east-west), Z (vertical)) was measured at Green Hill between 1 and 18 May 1980. The cable voltage data and the magnetometer data were individually recorded on magnetic tape using a microprocessor-based low-power digital data acquisition system with 15-bit resolution. The three components of the magnetic field and the voltage data were digitized at 2-s intervals. Timing (absolute and relative) was

Fig. 2 Average of five quiet day magnetic field variations (solid line). Calculated magnetic field variations produced by S_q ionospheric current systems (dashed line).

accurate in each data system to better than 1 s during the period of the measurements.

The time during which the cable measurements were made was relatively quiet geomagnetically⁸. Five of the most quiet days were selected to represent the S_q variation measured at Green Hill. These days, and their daily sum global geomagnetic activity indices ΣK_p , were: 3 May, -6; 4 May, -9; 5 May, -14; 17 May, +5; 18 May, -8. The averages of these five quiet days in the three magnetic field components measured at Green Hill are shown as solid lines in Fig. 2. These averages are obtained from the hourly mean values. The time dependences during a day show typical S_q patterns for this geomagnetic latitude, except for the local morning intervals in the H - and Z -components.

The dashed lines in Fig. 2 show the computed S_q curves expected on the basis of the spherical harmonic analysis of the potential for the daily variation by Chapman and Bartels⁹. We used the harmonic coefficients of Matsushita¹⁰ for location B on the model cable path in Fig. 1. The fit of the calculated S_q patterns using location B is quite good in the east-west component but is not good for the local morning observations in either the north-south or the vertical components. In addition, the magnitude of the S_q variation observed in the local afternoon in the north-south component is about a factor of two larger than that predicted by the model S_q calculations. These disagreements in the north-south and vertical components are

Fig. 3 Average of cable voltage variation for the five geomagnetic quiet days (solid line). Calculated induced voltage from all three magnetic components produced by S_q current system (dashed line). Calculated induced voltage from the horizontal magnetic component produced by S_q current system (dot-dashed line).

partially due to the closeness of the measurement site (~3 km) to the North Atlantic Ocean as well as to uncertainties in the spherical harmonic coefficients used in the S_q calculations. Note that data (not shown here) from our magnetometer station at Durham, New Hampshire, (44° N, 72° W geographic), located ~30–35 km from the ocean, show better agreement in the north-south component for the local morning S_q variations than do the Green Hill data.

The solid line in Fig. 3 shows the measured average variation of the cable voltage as a function of local time for the same five days as the magnetic field data of Fig. 2. This average was made using the hourly mean values and computing from them the five day average, in the same manner as was done for the S_q curves of Fig. 2. The relative expected induced voltage from induction by the S_q current system was modelled by considering the universal time (UT) change in the instantaneous S_q magnetic field pattern observed across the cable. To simplify the analysis, the S_q patterns at six locations (A–F in Fig. 1) were used for each hour of UT; the time derivative of the S_q magnetic field pattern was calculated at each of the six points. These six voltages ($V = -d\Phi(B)/dt$, where $\Phi = \mathbf{B} \cdot \mathbf{n}A$ is the magnetic flux through the surface S with area A) were averaged to represent the induced voltage across the cable at a given time. This induced voltage is of opposite polarity to the measured voltage. These calculated relative voltages (with changed signs) are superimposed on the measured voltage in Fig. 3. The dashed line is the calculated relative induction considering the total magnetic field changes from the S_q magnetic field pattern in all three components; that is, the total field contribution. The dot-dashed line is the calculated relative voltage considering only the horizontal component. The relative behaviour of this former calculated profile is a reasonably good approximation (with a 1- to 2-h

phase shift) to the observed voltage. (Induction currents from possible tidal^{2,11,13,14} and ocean current¹² effects are not considered important for this work^{2,11}.) A better agreement in terms of phase is obtained by assuming that the induction process that changes the Green Hill voltage occurs closer to the Green Hill end, rather than along the entire length of cable. Calculations of the S_q voltage pattern from points A–D (Fig. 1) show no phase shift. Physical understanding of this effect could be obtained by simultaneous measurements at both Green Hill and St Hilaire.

It is not possible to compare the magnitudes of the calculated voltage values with the observed S_q induced voltage without making some assumption as to the area of the Earth through which the induction process operates. An approximate equality between the relative calculated amplitudes and the observed induced voltage (~5 V) from the S_q pattern would imply an area of ~10¹² m² influenced by the induction.

Future work on induction by shorter-period geomagnetic variations should result in a better understanding of the geomagnetic induction phenomenon in varying geomagnetic conditions as well as at the different Earth locations over which a cable is laid.

We thank S. T. Brewer, B. H. Hamilton, and G. R. Ostby for advice and technical assistance, also G. Hailey and R. Foran for their support and help with our instrumentation at the Green Hill Terminal, and H. Wilhelmson for his careful reading of the manuscript.

Cambridge CB2 3EW, UK

The city of Herculaneum was buried under 20 m of pyroclastic deposits during the AD 79 eruption of Vesuvius, whose crater is only 7 km to the east. These deposits have been interpreted as the deposits of mudflows¹ or hot pyroclastic flows^{2–5}. Maury's studies⁶ of incinerated wood in Herculaneum demonstrate heating to at least 400 °C. We have studied the variation of remanent magnetism with temperature for specimens taken from the deposits, including specimens of the matrix material and of embedded lithic fragments. We conclude that the temperature of the deposit at emplacement is unlikely to have been greater than 400 °C, which further supports the interpretation of the pyroclastic deposits at Herculaneum as largely ignimbrites (hot pyroclastic flow deposits).

Ten oriented drill-core samples were collected from an excavation wall in the pyroclastic flow deposits at the western end of Herculaneum. The unit sampled is typical of the deposits

Fig. 1. Palaeomagnetic directions of pyroclastic samples from Herculaneum plotted on segments of equal-area projections. *a*, NRM directions; *b*, A components in lithic clast samples (●) and 400 °C thermally demagnetized NRM of matrix samples (▲); *c*, B components in lithic clasts (closed symbols on lower, open symbols on upper hemisphere of projection). Present geomagnetic field direction at sampling locality is dec = 359°; inc = 55°.

which bury the town and appears homogeneous and unstratified, consisting of a poorly sorted consolidated mixture of ash and pumice with local occurrences of angular lithic fragments of older volcanic rocks, limestone and brick. The volcanological stratigraphy at Herculaneum is detailed in ref. 7. The ash and pumaceous matrix is represented by samples H1 to H4; a variety of lithic fragments in addition to a large piece of light-coloured pumice, all between 10 and 20 cm in largest dimension, are represented by samples H5 to H10 (Table 1). The samples were taken over a stratigraphic interval of ~2 m, starting ~1 m above the excavation floor.

Most of the directions of the sample natural remanent magnetization (NRM) (Fig. 1*a*) group near to the present geomagnetic field for the site locality but four of the six samples of lithic fragments give divergent and scattered directions. The NRM intensities and Königsberger values (ratio of remanent magnetization to magnetization induced in present geomagnetic field) show only small variation amongst the samples of matrix but are more variable for the samples of lithic fragments (Table 1). In all samples, however, the remanent magnetizations exceed the induced components by anything between a factor of 4 and a factor of 69.

Progressive thermal demagnetization experiments show that the NRM of the the matrix samples consists of a single stable component similar in direction to the present orientation of the geomagnetic field and which persists up to demagnetization temperatures of 550 °C, when it disappears (Fig. 2*a*). In contrast, the NRM of all six lithic fragments is the result of two components of magnetization: A and B. The A component is identified in the initial stages of thermal demagnetization up to temperatures of 350–400 °C. The B component is the magnetization remaining in the final stages of thermal demagnetization, up to temperatures between 550 and 600 °C when the magnetization of the samples disappears (Fig. 2*b, c*). The directions of the A and B component (Fig. 1*b, c* and Table 1) in each lithic fragment sample are readily determined by regression analysis on the linear segments of the orthogonal vector end point demagnetization diagrams, as shown in Fig. 2. Where two specimens could be obtained for measurement from a drill-core sample of a lithic clast, both specimens provided similar magnetic characteristics.

The mean direction of the A component from the six lithic samples is dec = 359.2°, inc = 56.8°, $\alpha_{95} = 4.2^\circ$ and is statistically indistinguishable from the mean direction of the matrix samples (Table 1) or from the present geomagnetic field direction (dec = 359°, inc = 55°). Although the B components are well characterized and show good stability in individual lithic clasts, as a group they are randomly distributed at the 95% level of confidence (Table 1).

The lithic fragments evidently possessed a remanent magnetization before their incorporation in the pyroclastic deposit. This magnetization is now preserved as component B and may have originated as a thermal remanence (TRM) during initial cooling of the basalt and pumice, possibly a detrital remanence during initial deposition of the limestone, and either

J is intensity of magnetization; Q is Königsberger ratio; dec, inc, are declination, inclination of magnetization; means and statistics calculated using ref. 13; test for randomness from ref. 14.

*For $n = 6$, distribution is random if $r < 3.85$.

Fig. 2 Orthogonal projections of the successive end points of the magnetization vector (method from ref. 15) during progressive thermal demagnetization of representative samples from Herculaneum pyroclastic deposit. Solid symbols represent projection on the horizontal plane, open symbols on the north-south vertical plane. *a*, Matrix sample; *b*, basalt clast; *c*, limestone clast. Dashed lines in *b*, *c* are linear segments corresponding to A or B components.

a TRM or a chemical remanence when the brick was originally made. During incorporation in the pyroclastic deposit, physical rotation of the clasts resulted in the random distribution of their original (B) component magnetization.

After emplacement to their present position in the deposit, the lithic clasts became partially remagnetized, giving rise to component A which is statistically parallel in each clast. Given that the pyroclastic deposits probably experienced elevated temperatures, this magnetization is most likely a partial TRM—a supposition supported by the high Königsberger ratios. If a partial TRM mechanism is assumed for the A component, the magnetic unblocking temperatures measured in the laboratory can be used to approximate the maximum emplacement temperature from which the deposit cooled in place.

The curvature shown by some demagnetization trajectories (Fig. 2*b*) is interpreted as an overlap of blocking temperatures for magnetization components A and B. A conservative estimate for maximum unblocking temperature for component A would then correspond to the last point falling on the linear trajectory that defines this magnetization vector, which in Fig. 2*b* would be 350 °C. In other cases, (Fig. 2*c*), there is a strong inflection in the trajectories for components A and B and within the experimental uncertainties the maximum unblocking temperature for component A and the minimum unblocking temperature of the original component B coincide, at ~400 °C. The demagnetization behaviour of all lithic clast samples fell in either of these two categories and provided consistent unblocking temperature estimates for component A of between 350 and 400 °C.

Fig. 3 Fraction of magnetization remaining with progressive thermal demagnetization for the NRM, and for a TRM produced by cooling from 600 °C in the Earth's magnetic field, of a sample of pyroclastic matrix from Herculaneum.

This consistency over the various lithologies supports acquisition of a partial TRM at a common temperature and against elevation of blocking temperatures by other processes, for example, viscous magnetization or magnetochemical alteration. On the other hand, emplacement temperatures higher than 400 °C would have more completely reset the B component magnetization.

The fact that our maximum temperature estimate coincides closely with Maury's minimum temperature estimate strongly suggests that the emplacement temperature of the AD 79 Herculaneum pyroclastic deposit sampled was indeed close to 400 °C. The deposits can therefore be considered as largely ignimbrites (hot pyroclastic flows) which in general had not attained sufficiently high temperatures to cause pervasive welding. Other evidence for a high emplacement temperature includes the occurrence of vertical lithic-rich pipes, interpreted as degassing structures, and typical fine-grained ignimbrite basal layers to individual flow units²⁻⁵.

The matrix samples give only a single magnetization component which is similar in direction to the A component of the lithic clasts although the unblocking temperatures extend to 550–660 °C, ~200 °C higher than for component A. Given the close proximity of the sampling sites for the matrix and clast samples, it is unlikely that the higher maximum unblocking temperatures observed for the matrix material reflects a correspondingly higher emplacement temperature than indicated by the clast magnetizations. The unblocking temperature spectra of the matrix samples moreover are not consistent with the spectrum of a TRM produced by cooling a matrix sample from 600 °C in the Earth's field (Fig. 3). The NRM of the matrix material is therefore more likely to contain a contribution from a magnetization besides a partial TRM from 400 °C, perhaps a detrital remanence which, from the similarity in direction, was also acquired during emplacement of the pyroclastic deposit but which is typically carried by a grain assemblage with a wide distribution of blocking temperatures. Thus while bulk samples of the matrix may provide a valid record of geomagnetic field orientation corresponding to the time the deposits are formed, they are not as such readily useful for emplacement temperature determination.

Palaeomagnetic techniques have been used to discriminate hot and cold emplacement of pyroclastic deposits, for example, in Japan⁸, Santorini⁹ and the western US¹⁰. The Herculaneum pyroclastic flow can be categorized as a type III deposit (emplaced below their maximum blocking temperature but above the ambient temperatures) of Hoblitt and Kellogg¹⁰, of which they found no example. As palaeomagnetic techniques for emplacement temperature estimation depend largely on the common occurrence of magnetizable materials in pyroclastic deposits, the techniques should be of particular value in estimating emplacement temperatures of unwelded pyroclastic flow units in which lithological evidence for heating is ambiguous, as

at Herculaneum. The size range of lithic fragments suitable for such experiments can be extended downward for example, to matrix components, by use of microanalytical techniques^{11,12} while unblocking temperature profiles through very large lithic clasts may provide additional information on the thermal history of the pyroclastic deposit. Moreover, estimates of maximum emplacement temperature by the magnetic method, which are possible up to the Curie point of the constituent magnetic mineral (for example, 585°C for magnetite) can extend the range of temperature estimates obtained from studies of organic matter, which appear to be most definitive from 100°C to ~350°C (ref. 6).

Petrogenesis of Andean andesites from combined O-Sr isotope relationships

Russell S. Harmon

Isotope Geology Unit, Scottish Universities Research and Reactor Centre, East Kilbride G75 0QU, UK

Richard S. Thorpe & Peter W. Francis

Department of Earth Sciences, The Open University, Milton Keynes MK7 6AA, UK

The descent of the oceanic Nazca plate below the western margin of South America is responsible for the seismicity, tectonism and magmatism characteristic of Andean-type continental margins. Within this geological setting there is much debate concerning the petrogenesis of the calc-alkaline volcanic association. A thermal model for the descent of oceanic below continental lithosphere suggests that melting of subducted oceanic crust, the asthenospheric mantle wedge, and the lower crust might occur¹, and hence calc-alkaline volcanic rocks erupted at the surface in such regions might be derived from one or more of these sources. In the Andes, for example, Pichler and Zeil² have invoked partial melting of lower continental crust, while others³⁻⁵ envisage petrogenesis of andesites from sub-crustal mantle sources possibly in conjunction with crustal contamination⁶⁻⁹. We present here new O-isotope data for volcanic rocks from three contrasted volcanic settings in Ecuador, north Chile, and north-west Argentina. We then consider the significance of observed O-Sr isotope relationships, and attempt to evaluate the important factors in the petrogenesis of Andean andesitic lavas.

Active volcanism in the Andes occurs in three distinct regions: a northern zone (5°N–2°S), a central zone (16–28°S), and a southern zone (33–52°S); each having andesitic associations with distinctive chemical and isotopic compositions. The volcanic centres selected for study are in the northern and central volcanic zones. The northern zone in Ecuador and Columbia consists of composite volcanoes composed predominantly of basaltic andesite built on a 40–50-km thick sialic crust^{10,11}. Its sub-volcanic basement consists of metamorphic rocks of Cretaceous or older age¹². The central zone is characterized by composite volcanoes and large-volume ignimbrite sheets which overlie a thicker and more ancient sialic crust. Although the oldest rocks exposed adjacent to the active volcanic belt in southern Peru and northern Chile are Palaeozoic, Precambrian rocks occur to the west on the Peruvian coast¹³ and to the east below the Bolivian altiplano^{14,15} suggesting that the central volcanic belt is underlain by Precambrian rocks¹⁶. It has also been argued¹⁷ that the crust in the central Andes nearly doubled in thickness in the Cenozoic, so that the volcanoes of north Chile and south Peru rest on the central keel of the Andes where the crust is ~70 km thick. The volcanic setting in north-west Argentina is different to that to the west in southern Peru and northern Chile—here volcanic rocks occur on the 'Pampean Ranges' massif, a 'basin-and-range' province which comprises a wide variety of granitic and metamorphic rocks¹⁸ for which data indicate a late Precambrian to early Palaeozoic age¹⁹.

The Tertiary and Quaternary volcanic rocks of the Andes fall within the basaltic andesite–andesite–dacite classification of Peccerillo and Taylor²⁰. Chemical and isotopic compositions vary systematically across the Andean orogenic belt with SiO₂, K₂O and (⁸⁷Sr/⁸⁶Sr)_i increasing from west to east^{9,21-24} with calc-alkaline lavas generally enriched in K, Rb and Sr relative to P, Nb, Nd, Zr and Ti (refs 9, 25). There are, however, important inter-regional differences. The Ecuadorian lavas are olivine-pyroxene-bearing basaltic andesites with 53–61% SiO₂, 1.1–2.2% K₂O, 492–1,144 p.p.m. Sr, and 19–65 p.p.m. Rb (refs 7, 26, 27) whereas the lavas of north Chile and South Peru are predominantly pyroxene–hornblende-bearing andesites and

Fig. 1 Mean K₂O contents plotted against SiO₂ for volcanic centres in Ecuador, north Chile, south Peru, and north-west Argentina. The numbers shown by each data point are the average ¹⁸O/¹⁶O (upper) and ⁸⁷Sr/⁸⁶Sr (lower) ratios. The lines labelled 120, 150 and 250 km are inferred contours to the depth of the seismic zone³³. ▽, Basalt; ▲, basaltic andesite; ●, andesite; ■, dacite.

dacites with 56–66% SiO₂, 1.6–3.2% K₂O, 441–806 p.p.m. Sr, and 35–107 p.p.m. Rb (refs 17, 24). Thus, the respective mean SiO₂ and K₂O contents for the northern zone lavas are ~57 and 1.5% as compared with 60 and 2.2% for the western central zone lavas. By contrast, the Argentinean volcanic rocks cover the complete basalt–basaltic andesite–andesite–dacite spectrum. The basalt and basaltic andesites are olivine–pyroxene-bearing lavas largely from recent scoria cones and lava flows with 51–55% SiO₂, 2.0–2.7% K₂O, 477–1,048 p.p.m. Sr, and 45–75 p.p.m. Rb, whereas the andesites and dacites are pyroxene–hornblende-bearing lavas with 58–68% SiO₂, 2.9–4.2% K₂O, 236–645 p.p.m. Sr, and 52–269 p.p.m. Rb (ref. 28 and G. A. Kretzschmar, personal communication).

¹⁸O/¹⁶O ratios were determined for 33 samples from the volcanic centres of Chimborazo, Tungurahua, Sincholhua, Cotopaxi, Punalica and Calpi in Ecuador, San Pedro and San Pablo in north Chile, and Cerro Galan in north-west Argentina (Fig. 1) using the same powders for which chemical composition as well as Sr isotope and Nd isotope ratios had previously been determined. ¹⁸O/¹⁶O ratios are presented here relative to SMOW, with pertinent chemical and isotopic data: overall analytical precision is 0.1–0.2%. The combined O–Sr isotopic data are shown in Figs 1 and 2 with those of Magaritz *et al.*²⁹

All samples analysed were petrographically fresh and there is no chemical or isotopic evidence to suggest that the lavas had been subject to significant hydrothermal or deuteric alteration. Water contents are low, varying from 0.8–0.55 wt % for basalts and basaltic andesites to 0.34–1.37 wt % for andesites and dacites. Low-temperature alteration products, veining and phenocryst reaction rims are absent. However, an isotopic study of the south Peruvian andesites²⁹ showed that petrographically fresh andesitic lavas had plagioclase $\delta^{18}\text{O}$ values which were lower by an average of 0.6‰ than the corresponding whole-rock $\delta^{18}\text{O}$ values; this was attributed to a small amount of post-eruptive hydrothermal alteration. In the Ecuadorian samples plagioclase $\delta^{18}\text{O}$ values are equivalent to whole-rock $\delta^{18}\text{O}$ values, reflecting crystal–liquid equilibrium at the time of eruption.

Combined isotopic studies have proved useful in identifying the source(s) and tracing the evolution of plutonic and volcanic rocks formed at convergent plate margins. The generation of calc-alkaline magmas is a complex process which might involve partial melting of subducted oceanic crust, the overlying asthenospheric mantle wedge, and/or lower continental crust as well as subsequent fractional crystallization and contamination by upper continental crust during transit. Here the combined O–Sr isotopic data for the Andean lavas are used to comment on the petrogenesis of andesites.

The Ecuadorian lavas are the least evolved of the Andean volcanics and have the lowest ¹⁸O/¹⁶O and ⁸⁷Sr/⁸⁶Sr ratios (6.5–7.7‰; 0.7038–0.7044). The small ¹⁸O- and ⁸⁷Sr-enrichment observed in these rocks relative to typical mantle (6.0 ± 0.5‰; 0.702–0.704) could result from direct involvement of slab-released volatiles in the partial melting of overlying mantle during dehydration of the slab, by partial melting of small amounts of hydrothermally altered oceanic slab itself followed by re-equilibration in the mantle, or by partial melting of a pre-existing, alkali metasomatized mantle. Although these stable isotopic data are inadequate for a choice to be made between these alternatives, the overall chemical and isotopic characteristics of the Ecuadorian lavas suggest an alkali-enriched mantle source.

By comparison with the Ecuadorian lavas, ¹⁸O/¹⁶O and ⁸⁷Sr/⁸⁶Sr ratios are higher and more variable for the central zone volcanics in north Chile (8.0–10.8‰; 0.7059–0.7072), south Peru (7.0–8.6‰; 0.7054–0.7076), and north-west Argentina (8.3–10.7‰; 0.7054–0.7097). Because fractional crystallization cannot significantly alter the O- or Sr-isotopic composition of a magma, the observed differences between the northern and central volcanic zones must indicate a different or additional factor in the petrogenesis of the central zone lavas. If the isotopic character of the Ecuadorian lavas is representative of pristine

Fig. 2 Plot of $\delta^{18}\text{O}$ versus $(^{87}\text{Sr}/^{86}\text{Sr})_i$ for the Andean lavas analysed in this study. The solid curves I, IIa, IIb and III show the paths that would be followed during the process of combined assimilation-fractional crystallization for end-member compositions of hypothetical mantle ($^{18}\text{O} = 5.7\text{‰}$; $^{87}\text{Sr}/^{86}\text{Sr} = 0.703$) and an isotopically evolved crust ($^{18}\text{O} = 19\text{‰}$, $^{87}\text{Sr}/^{86}\text{Sr} = 0.735$). The curves, based on a ratio of Sr concentration in the end members of 5:1, are shown for three different (Sr cumulate/Sr melt) ratios (I, $\beta = 1$; II, $\beta = 2$ and III, $\beta = 3$) as well as two different ratios of cumulate to assimilated rocks (IIa, C:a = 9:1, IIb, C:a = 5:1) (for further discussion see ref. 34). ●, Ecuador; ●, North Chile; +, South Peru; ○, north-west Argentina. The number by each data point indicates the Sr content.

partial melts of a mantle source then those for the central zone lavas must reflect a different mantle or lower crustal source, or a contamination of magmas produced from the same mantle source.

Chemical and isotopic variations for the Andean lavas (Fig. 1) show that the K₂O–SiO₂ variations define linear trends which parallel those observed by Ninkovich and Hays³³ for island arcs and that for a given SiO₂ content there is a progressive increase in K₂O, ¹⁸O/¹⁶O and ⁸⁷Sr/⁸⁶Sr. Note that such increases occur in two directions on such a plot; enrichment of ¹⁸O and ⁸⁷Sr perpendicular to the depth contours of the seismic zone, reflecting inter-regional differences, and enrichment of ¹⁸O and ⁸⁷Sr parallel to depth contours indicating variation at a single volcano (for example, San Pedro–San Pablo, north Chile) or within a single volcanic province (for example, Cerro Galan, north-west Argentina). We interpret the former effect as indicative of source variation and the latter as contamination variation imposed on inherited source characteristics.

The most significant feature of the isotopic relationships for the Andean lavas is the positive correlation between ¹⁸O/¹⁶O and ⁸⁷Sr/⁸⁶Sr ratios (Fig. 1). Variations³⁴ of these two isotope ratios result from geologically independent processes, respectively the fractionation of stable O isotopes during the formation of low temperature sedimentary rocks at the Earth's surface and the radioactive decay of ⁸⁷Rb to ⁸⁷Sr. Thus a positive correlation

Fig. 3 The present crustal and mantle structure beneath the Andes at latitude 21°S; the known and inferred geological relationships; concepts regarding petrogenesis of Andean calc-alkaline magmas.

of ^{18}O and ^{87}Sr enrichment within a suite of genetically related igneous rocks must represent a major involvement with, or contamination by, continental crust. This correlation of O and Sr isotopic composition occurs within the Cerro Galan volcanic association of north-west Argentina, and also characterizes the overall O-Sr isotopic variation seen with the central and northern volcanic zones, although the relationship is different to those that have recently been described from two other areas of calc-alkaline magmatism, the Peninsular Range batholith of Southern California and Baja California³⁰ and the 'Newer' granites of the British Caledonides³¹. In each of these areas the positive correlations of $\delta^{18}\text{O}$ with $^{87}\text{Sr}/^{86}\text{Sr}$ extrapolate to O and Sr isotopic values representative of mantle compositions, suggesting that the calc-alkaline magmas in these three areas may have been largely derived from the mantle.

To evaluate the scale of the contamination variation, multi-component mixing models³⁴ have been used to evaluate the possible role of continental crust in the petrogenesis of the Andean lavas. Figure 2 shows the effects of a process of combined fractional crystallization-assimilation between a mantle and crystal end members with respectively low and high $^{18}\text{O}/^{16}\text{O}$ and $^{87}\text{Sr}/^{86}\text{Sr}$ ratios. Model lines are shown for ratios of the concentration of Sr in the cumulate material to that in the assimilated material (B) of 1 (curve I), 2 (curve II) and 3 (curve III). Curves II and IIb are respectively for bulk ratios of contaminant to assimilated material of 9:1 and 5:1. The positions of the curves in Fig. 2 depend on the exact compositions of the model end members. The low- ^{18}O , low- ^{87}Sr end member is reasonably well constrained within the limits Sr = 800–1,000 p.p.m.; $^{87}\text{Sr}/^{86}\text{Sr} = 0.702\text{--}0.704$, $^{18}\text{O}/^{16}\text{O} = 6.9 \pm 0.5$ considered characteristic of the mantle. By contrast, the composition of the high- ^{18}O , high- ^{87}Sr end member is arbitrary. The selected composition, Sr = 50–200 p.p.m.; $^{87}\text{Sr}/^{86}\text{Sr} = -0.735$, and $^{18}\text{O}/^{16}\text{O} = -19\%$ may be representative of the metamorphic and igneous rocks believed to be an important constituent of the central Andean Precambrian crust. However, the choice of a slightly different end-member composition would not change the shape of the curves, only the scale of the axes, and so require a larger or smaller proportion of crustal component to explain a given $^{18}\text{O}/^{16}\text{O}$ and $^{87}\text{Sr}/^{86}\text{Sr}$ value.

Figure 2 shows that the overall O-Sr isotopic trend for the Andean volcanic arc may be explained in terms of a process of combined assimilation and fractional crystallization between a

primitive, mantle-derived magma and isotopically evolved continental crust. This is best illustrated for the Cerro Galan volcanic suite of north-west Argentina. Francis *et al.*²⁸ considered two models for the Sr isotopic relationships (closed system bulk contamination and open system fractional crystallization-selective contamination) and concluded that the Sr-isotope variations were best explained by a small degree of selective Sr contamination of a magma ranging from basic to acidic in composition as the result of fractional crystallization. Figure 2 shows that the variation in $^{18}\text{O}/^{16}\text{O}$ ratios, 8.3–10.7%, together with an increase in $^{87}\text{Sr}/^{86}\text{Sr}$ ratio, 0.7054–0.7097, is consistent with a model involving fractional crystallization of a magma with the O- and Sr-isotopic characteristics of the least evolved sample (G49: $^{18}\text{O}/^{16}\text{O} = 8.4\%$; $^{87}\text{Sr}/^{86}\text{Sr} = 0.7054$) allied with up to 20% bulk assimilation. Although a well-defined O-Sr isotopic correlation is not present within the north Chilean and south Peruvian volcanics when considered individually, we feel this is likely to be due to the restricted compositional range of these lavas. However, it is possible that these variations might reflect primary characteristics of the source³², inherited characteristics of a source modified by crustal interaction³⁴ or the mixing of mantle and crustal magmas³⁵. However, the concomitant enrichment of ^{18}O and ^{87}Sr from the northern to central volcanic zones strongly indicates a crustal component to the central zone lavas.

As predicted by the assimilation fractional crystallization model, there is a general change in the major element chemistry coincident with the O-Sr isotopic variations (Fig. 1) as well as a general decrease in Sr content with increasing ^{18}O and ^{87}Sr content (Fig. 2). Figure 2 shows that most analyses cluster about the curves corresponding to a $\text{Sr}_{\text{cumulate}}/\text{Sr}_{\text{melt}}$ ratio of 2:1 and a cumulate to assimilate ratio of between 5:1 and 9:1. Therefore, if the assimilation-fractional crystallization process suggested by the O-Sr isotopic variations is valid, then the modelling implies that a large amount of cumulate must have formed during the evolution of the andesites and dacites from their basic precursors. Such cumulates might form parts of the batholithic intrusions inferred to be present below the Andes or might be present at depth within the lower crust. This suggestion is consistent with the recent estimate of the relative volumes of intrusive to extrusive rocks in the central Andes of Thorpe *et al.*³⁶, based on volumetric data.

Magaritz *et al.*²⁹ have recognized the necessity for an ^{18}O -enriched crustal component in the generation of andesitic lavas as a result of their O-Sr isotopic study of the Arequipa and Barroso volcanics of south Peru. After considering possible sources and by analogy with the Banda Arc, they concluded that the only reasonable source for the high ^{18}O component was continentally derived sediment which had been subducted and become involved in partial melting at depth. This argument was largely based on the absence of the $^{18}\text{O}/^{16}\text{O}$ – $^{87}\text{Sr}/^{86}\text{Sr}$ correlation which we have shown here to exist overall across the Andes. Even disregarding physical²⁸ and chemical²⁵ arguments against the involvement of subducted sediment in Andean calc-alkaline magma genesis, the isotopic data do not support such an idea. Certainly on mass balance considerations it is not feasible, given any reasonable proportions of components, to melt partially subducted-geosynclinal sediments ($\delta^{18}\text{O} \sim 13\%$; $^{87}\text{Sr}/^{86}\text{Sr} = 0.709$) together with altered oceanic crust ($\delta^{18}\text{O} \sim 7.9\%$; $^{87}\text{Sr}/^{86}\text{Sr} = 0.709$) and mantle to produce the ^{18}O - and ^{87}Sr -enriched lavas that occur in the central volcanic zone ($\delta^{18}\text{O} \sim 8\text{--}9\%$; $^{87}\text{Sr}/^{86}\text{Sr} \leq 0.711$). Likewise, the recent Pb-isotope data of Barreiro and Tilton³⁷ on the Arequipa and Barroso volcanics which are characterized by low $^{206}\text{Pb}/^{204}\text{Pb}$ ratios argue against contamination by subducted sediments—a crustal source is favoured.

The Andes are a classic setting in which to study the petrogenesis of calc-alkaline magmatism at destructive plate margins. Here the importance of subduction zone, mantle and crustal processes can be evaluated by chemical and isotopic techniques. The present data suggest an origin for andesitic magmas, illustrated in Fig. 3, which involves dehydration of the subducted

oceanic crust at depths of 60–100 km and alkali enrichment of the overlying asthenospheric mantle by LIL-enriched volatiles. The partial melting of this mantle then produces a basaltic melt slightly enriched in K, Rb and Sr relative to Zr and Ti and the REE as well as enriched in $^{87}\text{Sr}/^{86}\text{Sr}$ relative to $^{143}\text{Nd}/^{144}\text{Nd}$ and enriched in ^{18}O relative to normal mantle. This may be viewed as either a single-stage process in which alkali element enrichment occurs coincident with partial melting of primitive, homogeneous mantle, or as a two-stage process where a previously metasomatized mantle is partially melted to produce a calc-alkaline magma. Subsequent segregation of and diapiric uprise into the crust are followed by fractional crystallization and assimilation within the crust before eruption at the Earth's surface. In areas of relatively thin crust, such as in Ecuador, magmas rise to the surface as basaltic andesites largely unmodified by crustal contamination. However, in areas of thicker crust, such as in the central volcanic zone, the rising magmas are modified by a process of fractional crystallization allied with assimilation of isotopically evolved continental crust to produce andesites and dacites enriched in both ^{18}O and ^{87}Sr . Away from the subduction zone where partial melting occurs at depth in excess of 150 km, such as in north-west Argentina, magmas are probably derived from partial melting of the transformed oceanic slab with little or no volatile component so that the initial melts are enriched in both ^{18}O and ^{87}Sr relative to those magmas produced nearer the subduction zone from partial melting of the mantle. Here again slow rise of the basic melt through the thick crustal keel of the Central Andes provides an extended opportunity for fractional crystallization and crustal assimilation.

Isotopic work at the Scottish Universities Research and Reactor Centre and field work in the Andes by the Open University is supported by grants from the NERC. We thank G. A. Kretzschmar for unpublished K_2O data for Cerro Galan, J. Borthwick and J. Jocelyn for technical assistance, and C. J. Hawkesworth, H. P. Schwarcz and A. N. Halliday for helpful discussions. Miss J. McLean, Mrs E. Yuill, Mrs J. Bennett and D. MacLean helped to prepare the manuscript.

Thin-skinned tectonics in the northern Rhenish Massif, Germany

R. Meissner & H. Bartelsen

Institut für Geophysik, Universität Kiel, 23 Kiel, FRG

H. Murawski

Geol.-Paläontol. Institut, Universität Frankfurt, 6 Frankfurt/Main, FRG

A network of profiles in the Hercynian mountain system (Geotransverse Rhenoharzynikum) is needed to determine details of the geological structure and find the reasons for tectonic movements. Outstanding features within the mountain system such as the large fault zone along the southern boundary of the Hunsrück¹ and the left flank of the Rhinegraben have already been investigated by reflection seismology^{2,3}. We describe here a new reflection–refraction experiment carried out in 1978 in the most northern part of the Rhenish Massif, across the Stavelot–Venn Massif near Aachen (Fig. 1). While layers in the lower crust dip to the NNW, a strong upper reflector at 3–4 km depth shows a slight dip to the SSE and indicates a prominent fault zone near Aachen, known in Belgium as the Faille du Midi. Here, a comparable and apparently identical reflector was found some 100 and 175 km to the west of our profile. We interpreted this reflector as a prominent and well lubricated thrust fault along which a huge horizontal nappe displacement took place during the last stages of the Variscan orogeny.

A special arrangement of shot points and geophone patterns was used to investigate the complicated tectonics in the northern part of the Rhenish Massif. Each of the 15 shots for the 31-km long line was recorded by three synchronized 48-channel recording units, each set out at 7.5-km length spreads, leaving two gaps of ~4 km each which were filled by individual reflection–refraction stations (see Fig. 2). Explosive charges of 50–400 kg were fired at points along the line and at their extension to the SSE, providing a total length of 37 km in the subsurface with a six-fold coverage for the main part of the profile. This simultaneous recording of such a long geophone spread provided us with huge move-out times, that is with the possibility of determining the velocity–depth structure with a very high accuracy from the reflection move-out. It was also a powerful method of determining the (predominantly horizontal) velocity from the evaluation of the first (refracted) arrivals which appeared as 12 overlapping refraction branches for the sixfold reflection coverage, hence providing sufficient redundancy for calculating near-surface velocities and corrections. (Details of this method and the interpretation work will be given elsewhere.) Figure 3 shows a stacked section of the upper 3 s two-way travel time involving the upper reflector. Strongly varying velocities within the steeply dipping surface layers are responsible for some remaining apparent undulations of the reflector. To determine its nature the following conclusions can be made.

The strong, high-frequency reflector indicates a considerable jump in impedance and hence in seismic velocity. The velocity cannot jump to a thick layer with a higher velocity because the first arrivals do not show any considerable velocity increase up to distances of 45 km, nor can the velocity jump to a thick layer with a lower velocity because no break in the first arrivals is observed. Hence, the strong reflectivity must result from a very thin layer of the order of a fraction of the dominant wavelength. Its thickness, estimated to be between 40 and 100 m, agrees both with the continuity of the first arrivals and with the single-wavelet, good quality of the reflector. A thin layer of higher velocity seems improbable because at least some high-frequency

Fig. 2 Profile field set-up. ●, Shotpoints; ▲, additional wide-angle stations. Hatching on the schematic reflector R shows the 'subsurface coverage' for the first shotpoint, corresponding to the geophone spread of three recording units. Signals from all shotpoints were recorded by the geophone spreads resulting in a sixfold coverage of reflectors.

events with higher velocities would be expected in this case. The only consistent solution, therefore, is provided by a thin layer with lower velocities. Such a layer, together with the shape and the direction of the reflector which points directly towards a prominent surface fault system in the Hohes Venn area, strongly suggests that the reflecting interface resembles a thrust fault with

indications of large nappe displacement to the north-west. Figure 4 shows a geological cross-section of the upper part of the area under investigation, containing the reflector as its lower boundary.

The interpretation of the reflector as a prominent thrust fault is supported by petrological evidence, seismological and geodetic observations and by other seismic reflection results. Thrust faults, for example, generally exhibit high pore pressure, grain diminution and generally, a hydrolytic weakening⁴. Although these effects lead to a decrease in velocities^{5,6}, a high pore pressure which considerably reduces the effective pressure might have the strongest effect on the velocity decrease within a thin zone of deformation⁷. Hence it seems important that the fault zone is still seismically active in the correct overthrust direction as seen from a fault plane solution of a quake in the thrust fault area⁸. Also, an increased vertical uplift has been observed in the Hohes Venn area⁹. Today's stress pattern¹⁰ seems to be similar to that during late Variscan time, hence probably reactivating the old fault zones. Note that reflection experiments of the Famenne area, ~100 km WSW of the

present profile, have also revealed a prominent reflector at roughly the same depth as our presumed thrust fault and also dipping gently to the SSE. A comparable reflector has also been found some 175 km to the west¹² and even farther. Figure 5 shows the approximate depth of this reflector in the area of investigation. The identified reflector, interpreted as a thrust fault, covers a large area and may even extend laterally to the east and west and to greater depths to the south where no seismic investigation has been carried out.

Recent investigations in the southern Appalachians by the COCORP group¹³ and in the northern Appalachians have shown similar pronounced, shallow and slightly inclined reflectors. In the southern part they are interpreted as thrust faults on which the crystalline basement of the Appalachians has been thrust at least 260 km towards the North American continent¹³⁻¹⁵.

We do not know whether the thin-skinned nappe in our test area in the Variscides was transported over a comparably large distance, but this possibility must be considered. The lateral dimensions of the nappe of at least 200 km—a lower limit, only marked by the available seismic reflection observations—indicates that large and regional compressive forces were acting during the last phases of the Variscan orogeny. We also do not know whether a pattern of approaching and colliding island arcs and microcontinents, as apparently involved in the creation of the southern Appalachians¹⁵, was also responsible for the formation of the complex Variscan tectonics. Certainly, here the deformation front also moved from SW towards the NW—towards a large continental area.

Extensive nappe displacements are well known from virtually all orogenic belts from Caledonian to recent compressional regimes, for example, Alpine-Himalayan; but in most cases the depth, the dimension and the structure of them remain unknown. For parts of the Appalachians^{14,15}, and now also for parts of the northwestern Variscides the character and the depths of the thrust planes have been revealed and their nature analysed from reflection seismology. The formation of thin-skinned nappes riding over a rather undeformed subsurface along plane, well lubricated thrust faults may indicate a final stage of compressional tectonics.

We thank P. Ziegler, for helpful discussions and our colleagues of the Geological Institute of the RTHW Aachen for the geological profile.

Group selection is implicated in the evolution of female-biased sex ratios

Robert K. Colwell

Department of Zoology, University of California, Berkeley, California 94720, USA

Female-biased sex ratios are common among arthropods that mate in small groups with episodic dispersal¹⁻³. When breeding groups are founded by more than one female, individual (within-group) selection favours an unbiased (1:1) sex ratio, regardless of group size and degree of inbreeding (or sibmating), and regardless of the intensity of local competition among siblings for mates. On the other hand, female-biased sex ratios are favoured by group selection in randomly structured populations. Existing treatments of the evolution of female-biased sex ratios^{1,2,4-6} correctly predict the result of evolution, but do not make clear that it is a balance between opposing forces at two levels of selection³. I now show this to be so.

Fisher⁷ pointed out that in a random-mating population with a biased sex ratio, an individual of the rarer sex leaves more progeny, on average, than an individual of the commoner sex, so that frequency-dependent selection favours equal investment in sons and daughters. Hamilton¹ modelled the evolution of

Table 1 Model for the evolution of female-biased sex ratios as a balance between the opposing forces of individual and group selection

For all breeding groups, let

- n = number of inseminated females founding each group
 a, b = proportion of sons among the progeny of each A-type (a) or B-type (b) female
 r = number of progeny produced by each female, regardless of type
 $\bar{p}$ = proportion of founding females that are A-type in the global population
 p' = proportion of grandmaternal gene copies that are due to A-type founding females in the global population

I Individual selection (within groups)

In a group founded by n inseminated females, of which $x = p_x n$ are A-type (each producing ar sons) and $(1 - p_x)n$ are B-type (each producing br sons), the numbers of sons and daughters among the group's progeny (F_1) are

$$s_x = n[p_x a + (1 - p_x)b] \quad \text{and} \quad d_x = n[p_x(1 - a) + (1 - p_x)(1 - b)] \quad (1)$$

Now the F_1 mate at random within the group, with mating probabilities

$$\begin{aligned} A\delta \times A\varphi: M_{AA} &= p_x^2 \left(\frac{a}{s_x} \right) \left(\frac{1 - a}{d_x} \right) r^2 n^2 \\ A\delta \times B\varphi: M_{AB} &= p_x(1 - p_x) \left(\frac{a}{s_x} \right) \left(\frac{1 - b}{d_x} \right) r^2 n^2 \\ B\delta \times A\varphi: M_{BA} &= (1 - p_x)p_x \left(\frac{b}{s_x} \right) \left(\frac{1 - a}{d_x} \right) r^2 n^2 \\ B\delta \times B\varphi: M_{BB} &= (1 - p_x)^2 \left(\frac{b}{s_x} \right) \left(\frac{1 - b}{d_x} \right) r^2 n^2 \end{aligned} \quad (2)$$

$$M_{AA} + M_{AB} + M_{BA} + M_{BB} = 1$$

where $A\delta$ means a son of an A-type founder, $B\varphi$ a daughter of a B-type founder, and so on. The proportion of grandmaternal gene copies among the F_2 that are due to A-type founders is

$$p'_x = M_{AA} + \frac{1}{2}(M_{AB} + M_{BA}) = \frac{p_x^2 a(1 - a) + \frac{1}{2}p_x(1 - p_x)[a(1 - b) + b(1 - a)]}{[p_x a + (1 - p_x)b][p_x(1 - a) + (1 - p_x)(1 - b)]} \quad (3)$$

and the total number of F_2 gene copies due to A-type founders is

$$p'_x V_x = p'_x r d_x \quad (4)$$

assuming diploidy.

For a particular breeding group, let

- x = number of founding females that are A-type (the rest, $[n - x]$, are B-type)
 $p_x = x/n$ = proportion founding females that are A-type
 p'_x = proportion of grandmaternal gene copies that are due to A-type founding females
 s_x, d_x = total number of sons (s_x) or of daughters (d_x) produced by all n founding females
 $V_x = r d_x$ = total number of grandprogeny (F_2) produced by the daughters of all n founding females (group productivity)
 π_x = probability that a particular group is founded by x A-type and $(n - x)$ B-type females

II Integration of individual selection with group selection

In the global population, the distribution of group composition is assumed to be binomial, so the probability that a group will have x A-type females among its n founders is

$$\pi_x = \binom{n}{x} \bar{p}^x (1 - \bar{p})^{n-x} \quad (5)$$

The average number of F_2 gene copies, per group, due to all founding females is

$$\bar{V} = \sum_{x=0}^n \pi_x V_x = n r^2 [\bar{p}(1 - a) + (1 - \bar{p})(1 - b)] \quad (6)$$

since $E[p_x] = \bar{p}$. The average number of F_2 gene copies, per group, due to A-type founding females is

$$\sum_{x=0}^n \pi_x p'_x V_x \quad (7)$$

Therefore, the proportion of grandmaternal gene copies in the F_2 that are due to A-type founding females in the global population is

$$\bar{p}' = \frac{\sum_{x=0}^n \pi_x p'_x V_x}{\bar{V}} \quad (8)$$

For example, for $n = 2$,

$$\bar{p}' = \frac{\bar{p}(1 - \bar{p})[(2a + b)(1 - a) + a(1 - b)] + \bar{p}^2(1 - a)}{\bar{p}(1 - a) + (1 - \bar{p})(1 - b)} \quad (9)$$

female-biased sex ratios for a population structured into randomly initiated groups, each founded by n inseminated females, whose offspring mate locally among themselves and then disperse to found new groups. For such a population, Hamilton showed that an autosomal gene that causes its female bearer to produce ar sons among her r progeny, where $a = (n - 1)/2n$, will be 'unbeatable' by a gene coding for any other sex ratio (diploidy, complete mating and equal investment per offspring assumed). Thus, the optimal progeny sex ratio is $1/4$ sons with $n = 2$ founding females, rising asymptotically toward $1/2$ sons with increasing n . A solitary founding female ($n = 1$) should produce the minimum number of sons required to inseminate her daughters.

Hamilton¹ and others^{4-6,8} have suggested that daughter-biased progenies are an adaptive response to selective pressures on the mother, serving to reduce 'local mate competition' (LMC) among her sons. By this argument, the increasing probability that brothers will compete for the same mates, as the number of sibships becomes smaller, is countered by a progressive decrease in the proportion of sons. Members of a local breeding group, such as the wasps in a single fig² or host pupa⁶, or the hummingbird flower mites in a single inflorescence³ are highly inbred, relative to the global population of which they are a part. Hamilton's¹ early emphasis on inbreeding, and Maynard Smith's⁴ reformulation of Hamilton's LMC model in terms of the proportion of matings that are between siblings, may have suggested to some authors⁸⁻¹⁰ that inbreeding (or sibmating) itself somehow provides a mechanism for the evolution of

daughter-biased progenies as an individually advantageous adaptation, reducing sibling competition for mates.

For the case of more than one founding female ($n > 1$), a simple algebraic model for the evolution of progeny sex ratio (Table 1) indicates that (1) LMC itself cannot select for female-biased progenies, (2) inbreeding (sibmating) is not relevant to the problem, and (3) group selection (differential productivity of genetically different groups) is required for the evolution of female-biased sex ratios.

In the model, each generation of local mating among the progeny of n founding mothers is followed by population-wide mixing and dispersal of their inseminated daughters. Two maternal phenotypes ('A-type' and 'B-type') compete, each producing a different, fixed progeny sex ratio (a and b , respectively, as proportion of sons). The fitness of a founder is measured in terms of the gene copies she leaves among grandprogeny^{1,4,6,11}. Figure 1 shows that the fitness of a 'fisherian' founder, producing an unbiased progeny sex ratio ($b = 0.5$), always exceeds the fitness of a 'hamiltonian' founder, producing a daughter-biased sex ratio ($a < 0.5$), regardless of the number of founders, initial proportion of the two types and degree of female bias in hamiltonian progenies¹. Because the degree of selective advantage of fisherian females depends only on their proportion among founders, relative fitness of the two types is completely unaffected by the level of inbreeding or sibmating, and by the intensity of competition among brothers for mates, which are functions of the number of founders, given a and b . Individual selection on females whose offspring breed in local

groups with the offspring of other founders, however few, cannot favour daughter-biased progenies.

How, then, can female-biased sex ratios evolve? If the dispersal pool includes more than one sex-ratio phenotype, local groups will vary by chance in the frequency of the phenotypes among founders. Within each group, the relative fitness of fisherian founders exceeds that of hamiltonian founders. However, groups with higher-than-average initial frequencies of hamiltonian females produce a greater-than-average absolute number of grandprogeny, simply because their founders jointly produce more daughters (and fewer sons) than

Table 2 Individual and group selection in the evolution of female-biased sex ratios: a numerical example with $n = 4$

	Group 1	Group 2
I Initial composition of groups		
A. Number of hamiltonian ($a = \frac{1}{2}$) founders: x	3	1
B. Number of fisherian ($b = \frac{1}{2}$) founders: $(n - x)$	1	3
C. Proportion hamiltonian founders: p_x	0.75	0.25
II Contribution of founders to grandprogeny:		
Individual selection		
A. Proportion of grandmaternal gene copies due to		
1. Each hamiltonian founder	0.2470	0.2471
2. Each fisherian founder	0.2591	0.2510
3. All hamiltonian founders: p'_x	0.7409	0.2471
4. All fisherian founders: $(1 - p'_x)$	0.2591	0.7529
B. Fitness of a hamiltonian founder relative to a fisherian founder	0.9533	0.9845
III Differential productivity of groups:		
Group selection		
A. Total grandprogeny produced by each group: V_x	$2.375r^2$	$2.125r^2$
B. Number of grandprogeny gene copies within each group due to		
1. Each hamiltonian founder	$0.5865r^2$	$0.5251r^2$
2. Each fisherian founder	$0.6154r^2$	$0.5333r^2$
3. All hamiltonian founders: $p'_x V_x$	$1.7596r^2$	$0.5251r^2$
4. All fisherian founders: $(1 - p'_x) V_x$	$0.6154r^2$	$1.5999r^2$
IV Number of gene copies among pooled grandprogeny		
A. Due to each hamiltonian founder: $\frac{1}{4}(1.7596 + 0.5251)r^2 =$	$0.5712r^2$	
B. Due to each fisherian founder: $\frac{1}{4}(0.6154 + 1.5999)r^2 =$	$0.5538r^2$	

Individual and group selection in the evolution of female-biased sex ratios. This example is based on an arbitrary initial composition of groups. Two groups are formed by sampling from a founder pool that consists of half fisherian (F) and half hamiltonian (H) inseminated females. The groups differ in the frequency of the two types (line IC) but together reflect the (equal) frequencies in the founder pool. Each female in each group then produces r progeny, of which $1/2 r$ are sons, for each fisherian mother, and $3/8 r$ are sons, for each hamiltonian mother. The progeny mate at random among themselves within each group (all females are inseminated). Computing fitness within groups as the expected number of grandmaternal gene copies due to each founding female (lines IIB, 1, 2), it is evident that the individual fitness of each fisherian female exceeds that of each hamiltonian female within groups (line IIB). This is true for any mixed group (Fig. 1). On the other hand, group fitness—the total number of grandprogeny produced (line IIIA)—is greater for the group with the higher initial frequency of hamiltonian females, because its founders jointly produce more daughters (and fewer sons) than do the predominantly fisherian founders of the other group. Because the more productive group is mostly hamiltonian, when the number of gene copies due to each of the two types of founders is evaluated among the pooled grandprogeny of the two groups, the hamiltonian founders prove to have contributed more than the fisherian founders (lines IVA, B), in spite of the selective disadvantage of hamiltonian founders within each group. The force of group selection depends on the variance in initial composition of groups, here arbitrarily established to make a point. In fact, random (binomial) variation is sufficient for the force of group selection to exceed that of individual selection^{3,13}. Greater-than-binomial variance only increases the effect^{2,13}. In terms of Price's^{2,14} hierarchical model of selection, the fitness of groups (V_x) co-varies positively with the proportion of hamiltonian founders that initiate them (p_x), whereas the fitness of individuals within groups co-varies negatively with possession of the hamiltonian trait (or, genetically, with the number of hamiltonian alleles an individual carries): p'_x is inevitably less than p_x . Thus, female-biased sex ratios are opposed by individual selection, but are favoured by group selection.

Fig. 1 Fisher's⁷ sex ratio principle. The selective disadvantage of producing female-biased progeny. A group is founded by hamiltonian females in proportion p_x , each producing proportion $a < 0.5$ sons, and by fisherian females in proportion $(1 - p_x)$, each producing half sons and half daughters. Here, the proportion of grandmaternal gene copies in the grandprogeny that are due to the hamiltonian founders, p'_x (computed by equation (3), Table 1) is plotted as a function of a for several values of p_x . The figure demonstrates that p'_x is inevitably less than p_x : the fitness of fisherian founders always exceeds that of hamiltonian founders in a mixed group. Note that the number of founding females (n , group size) plays no part in this result. Fisher's principle operates with equal force in random-mating groups or populations of any size, whether initiated

average. The crucial point is this: when genetic contributions to the grandprogeny of randomly initiated groups are pooled by dispersal, hamiltonian founders prove to have made a greater per capita contribution than fisherian founders, even though within every mixed group the reverse is true. Table 2 provides a numerical example of this phenomenon.

In general terms, the global proportion of grandmaternal gene copies in the grandprogeny that are due to A-type founders is a productivity-weighted average of local (within-group) proportions, derived in part II of Table 1 on the assumption of random (binomial) variation among groups in the initial frequency of A-type and B-type founders. When A-type females are optimally hamiltonian [$a = (n - 1)/2n$] it is easily shown numerically (for example, with equation (9), Table 1) that the global proportion of grandmaternal gene copies due to hamiltonian females is greater than the proportion of hamiltonian females among group founders, regardless of the progeny sex ratio produced by B-type founders and initial frequencies of the two types. (Hamilton¹ obtained this result analytically by direct optimization.) In other words, whatever the mode of inheritance, optimally hamiltonian alleles will increase in frequency relative to fisherian (or any other) alleles in a randomly structured population. The present model permits a more general statement: if $b < a \leq (n - 1)/2n$ or if $b > a \geq (n - 1)/2n$, A-type females prevail at any starting frequency; if $a < (n - 1)/2n < b$, a frequency-dependent stable polymorphism exists (for example, if $n = 3$, $a = 0.1$, and $b = 0.6$, then $\bar{p}' = \bar{p} = 0.48$).

The force of individual selection is independent of the number of founders (n) (Fig. 1), whereas the force of group selection increases with genetic variation among groups^{12,13}, which becomes greater as n decreases, producing increasingly female-biased sex ratios. If among-group variation in progeny sex ratio is suppressed, or if it is permitted, but differential productivity is eliminated by the imposition of a carrying capacity, female-biased sex ratios cannot evolve, regardless of n , and therefore regardless of the level of inbreeding, sibmating and local mate competition³.

Growth hormone stimulates adrenal steroidogenesis in the fetus

The 'surge' of corticosteroid in fetal plasma during late gestation has been implicated in the initiation of parturition and the maturation of enzyme systems in organs such as the lung, liver, adrenal medulla and thyroid¹⁻⁵. But in all species studied, the mechanism responsible for increased secretion in the fetus remains unclear. The hormone adrenocorticotropin (ACTH) is well established as the primary regulator of adrenocortical cellular growth and secretory function during fetal and adult life⁶. However, no increase in fetal plasma ACTH has been observed before the corticosteroid surge in sheep or humans^{7,8}, although differential responsiveness of the fetal adrenal cortex to ACTH at various gestational ages and a possible role of extra-adrenal inhibitory factors have been proposed⁹⁻¹². The possible steroidogenic effect of α -melanocyte-stimulating hormone (α MSH) on fetal adrenocortical function is controversial¹³⁻¹⁶, and we could not demonstrate any such action in fetal lamb or rabbit^{17,18}. Prolactin and growth hormone (GH) potentiate the steroidogenic effect of ACTH in adult rats¹⁹⁻²² but prolactin had no such effect in fetal lamb¹⁷. We have investigated the steroidogenic properties of GH, and report here that it stimulates adrenal steroidogenesis in the fetal but not maternal rabbit *in vitro* and in fetal but not maternal sheep *in vitro* as well as *in vivo*.

We used pregnant New Zealand White rabbits of known gestational age (g.a. 25-30 days, term 31 days, $n=8$) and Columbia-Suffolk strain ewes (g.a. 140-144 days, term 150 days, $n=5$). Each was killed by intravenous pentobarbitone and after hysterotomy, the fetuses were rapidly removed. Adrenal glands were removed *in toto*, without disrupting the capsule, and bathed in culture medium M199 with Hank's salt solution (Gibco) containing 2.2 mM calcium chloride. Adrenals were pooled within each litter of rabbits. Glands were trimmed of fat and connective tissue, minced when necessary and bathed in 5 ml of medium M199 containing 2.5 mg ml⁻¹ of lyophilized trypsin (Worthington), which digests adrenal medullary cells but leaves adrenocortical cells intact. We previously described¹⁸ the details of isolating dispersed viable adrenocortical cells by a modification of Sayers' technique²³. We then incubated 3×10^4 cells in 150 μ l (rabbit) or 10^5 cells in 200 μ l (sheep) of the culture

Fig. 1 Fetal lamb plasma corticosteroid concentrations before and after HGH infusion (shown by shaded bar). Age of lambs: ▲, 138 days; ●, 143 days; ×, 139 days; ○, 137 days.

medium, in duplicate with 50 μ l of phosphate buffer (0.01 M monobasic sodium phosphate, 0.9% NaCl, pH 7.4), adding human GH (HGH, National Pituitary Agency, NIH-HS 2243E) or synthetic ACTH₁₋₂₄ (Organon), the biologically active portion of the intact hormone ACTH₁₋₃₉, in the buffer. The incubation was performed in polystyrene tubes (12 $\times$ 75 mm) in a water bath at 37 °C under a mixture of 5% CO₂ and 95% O₂ for 2 h, after which the cells were removed by centrifugation at 300g for 10 min. Aliquots (50 μ l) of supernatant were removed, in duplicate, to measure corticoid production. Response to ACTH₁₋₂₄ served as the control for the steroidogenic response of the cell preparation. Corticosteroids were measured by a specific radioimmunoassay (RIA)^{24,25}. Because rabbit adrenals secrete both cortisol and corticosterone²⁶, an antibody (Radioassay System Catalogue 147) that reacts 100% with both hormones was used with rabbit adrenal cells, but because cortisol is the major corticoid in sheep²⁷, an antibody (Radioassay System Catalogue 137) that cross-reacts 100% with cortisol and minimally with other corticoids was used with sheep adrenal cells. The results represent total corticosteroid production by dispersed rabbit and sheep adrenocortical cells.

For *in vivo* studies, pregnant Columbia-Suffolk strain ewes of known gestational age and adult non-pregnant sheep were used. Pregnancy was confirmed by X-ray analysis between 85 and 90 days of gestation. The maternal and fetal carotid artery and jugular vein were catheterized²⁸ at least 1 week before the experiment. At 137, 138, 139 and 143 days of gestation, 20 μ g

Table 1 Basal corticosteroid production and increment above basal from hormone stimulation by fetal and maternal rabbit adrenocortical cells

Corticosteroid production (ng per 3×10^4 cells per 2 h)		
	Fetus ($n=8$)	Mother ($n=4$)
Basal	3.69 ± 0.66	3.38 ± 0.52
Increment above basal		
ACTH (25 μ g ml ⁻¹)	2.69 ± 0.32	2.80 ± 0.26
ACTH (125 μ g ml ⁻¹)	3.96 ± 0.47	3.85 ± 0.17
HGH (1.25 μ g ml ⁻¹)	3.30 ± 0.37	-0.05 ± 0.08
HGH (2.5 μ g ml ⁻¹)	4.59 ± 0.27	-0.04 ± 0.05

Values are mean $\pm$ s.e.m.

of HGH in 8 ml of normal saline was infused for 1 h through the fetal jugular vein. Fetal arterial blood (1 ml) was drawn at timed intervals before and after starting HGH infusion as indicated in Fig. 1; pH, pO_2 and pCO_2 were measured before and after infusion and were similar and in the normal range of our experimental animals. To exclude the effects of stress due to saline infusion, two animals earlier infused with HGH were infused with 8 ml of normal saline through the fetal jugular vein at 140 and 141 days of gestation and fetal corticosteroid concentration in plasma measured. We also infused HGH into catheterized adult sheep ($n = 3$) using the same protocol. With-drawn blood was immediately centrifuged at 500g for 10 min at 4°C and plasma stored at -20°C until measurement of corticosteroid concentrations²⁵. Plasma concentrations of HGH achieved *in vivo* were measured by RIA²⁹ in two fetal and one adult sheep before and after HGH infusion.

The mean basal production of corticoids, and the increase (mean $\pm$ s.e.m.) due to hormonal stimulation in rabbit and sheep adrenal cells are shown respectively in Tables 1 and 2. Although fetal cells from both species significantly increased steroidogenesis under the influence of ACTH₁₋₂₄ or HGH, the maternal cells responded to ACTH₁₋₂₄ only. Furthermore corticoid production by fetal rabbit and fetal sheep cells after incubation with 2.5 μ g ml⁻¹ of HGH was significantly higher than after 1.25 μ g ml⁻¹ (paired *t*-test $P < 0.02$).

Basal plasma corticosteroid concentrations in fetal lamb were significantly higher than in adult sheep (Figs 1, 2), but in both were within range reported by others³⁰⁻³². Plasma corticosteroid concentrations increased between 60 and 350% above basal after infusion of HGH in all four fetal lambs (Fig. 1). No such increase was noted in fetuses infused with saline or in adults infused with HGH (Fig. 2). Basal fetal and adult plasma HGH concentrations were less than the sensitivity of the assay (0.1 ng ml⁻¹), indicating minimal cross-reaction between endogenous ovine growth hormone and the HGH, especially as GH concentrations in ovine fetal plasma are high^{33,34}. Fetal lamb plasma HGH concentrations at the end of infusion (+60 min) were 15.3 and 25 ng ml⁻¹ while adult sheep plasma HGH concentration was 2.1 ng ml⁻¹.

The HGH we used is a highly purified immunochemical. Because maternal adrenal cells showed no steroidogenic response, unlike fetal cells, contamination of HGH with biologically active ACTH seemed unlikely. To confirm this assumption, the buffer and 2.5 μ g of HGH in the buffer were assayed for ACTH by RIA at Nichols' Institute³⁵. The ACTH concentrations in HGH plus buffer were the same as those in the buffer alone. Contamination with α MSH seemed unlikely for the following reasons. Using the same dispersed cell system and RIA techniques, we have observed no steroidogenic effect of α MSH in concentrations from 8 to 800,000 pg ml⁻¹ in either fetal sheep or rabbits at various gestational ages^{17,18}. Similarly, infusion of 75 μ g of synthetic α MSH (Bachem) in chronically catheterized fetal sheep at 127-130 days of gestation ($n = 4$) produced no increase above basal fetal plasma corticosteroid concentrations¹⁷. As a direct steroidogenic effect of HGH was observed *in vitro*, the increase in fetal plasma corticosteroid

Fig. 2 Adult sheep plasma corticosteroid concentrations before and after HGH infusion (shown by shaded bar).

Table 2 Basal corticosteroid production and increment above basal from hormone stimulation by fetal and maternal sheep adrenocortical cells

Corticosteroid production (ng per 10 ⁵ cells per 2 h)		
Basal	Fetus ($n = 5$)	Mother ($n = 3$)
Increment above basal	1.79 $\pm$ 0.42	1.92 $\pm$ 0.59
ACTH (25 pg ml ⁻¹)	2.87 $\pm$ 0.63	5.04 $\pm$ 1.54
HGH (1.25 μ g ml ⁻¹)	3.08 $\pm$ 0.86	-0.15 $\pm$ 0.17
HGH (2.5 μ g ml ⁻¹)	5.33 $\pm$ 1.1	0.13 $\pm$ 0.19

Values are mean $\pm$ s.e.m.

observed *in vivo* is unlikely to have been due to ACTH released from the fetal pituitary.

Although no data are available for the rabbit, fetal plasma GH concentrations are very high compared with those during neonatal and adult life in sheep^{33,34} and humans³⁶. Because GH does not cross the placenta and the metabolic clearance rates in the fetal and neonatal period are similar³⁷, high fetal plasma concentrations probably represent increased secretion by the fetal adenohypophysis. The physiological significance of high fetal plasma GH concentrations is unclear; it does not seem to be essential for somatic growth³⁷. Our findings provide the first experimental evidence that GH directly influences adrenal steroidogenesis during fetal life. Although concentrations of HGH achieved *in vivo* were within the physiological concentrations of ovine GH observed in fetal (up to 250 ng ml⁻¹) and adult sheep plasma^{33,34}, the concentrations of HGH tested *in vitro* were one log order greater. Using entire adrenal glands rather than dispersed cells, collected from fetal rabbits at 24-27 days of gestation, Rudman *et al.* observed no increase in corticosterone production due to HGH stimulation¹⁶. The discrepancy with our results may be due to the different design of the experiments, the different gestation, the different RIA or a combination of these factors.

The respiratory burst of phagocytic cells is associated with a rise in vacuolar pH

Anthony W. Segal*, Michael Geisow†, Rodolfo Garcia*, Angela Harper* & Robert Miller‡

‡ Department of Zoology, University College London, London WC1E 6BT, UK

Neutrophil leukocytes are the body's major defence against bacteria, which they phagocytose and kill. It has been found that phagocytosis and killing are accompanied by a dramatic rise in non-mitochondrial respiration^{1,2}; and that the efficiency of killing is impaired in the absence of oxygen^{3,4}. It is also impaired in neutrophils from patients with chronic granulomatous disease (CGD), where the respiratory burst is absent⁵. This has been difficult to reconcile with their normal content of granule proteins that kill bacteria *in vitro*⁶. Indeed, CGD cells are essentially normal both morphologically and constitutionally^{7,8} except that they lack a functional very low potential cytochrome *b* (*b*₂₄₅)⁹, which is a component of the oxidase system responsible for the respiratory burst of normal cells^{10,11}. Activation of the oxidase is associated with the generation of various reduced oxygen species¹²⁻¹⁶ which have been widely thought to be responsible for the killing of phagocytosed microorganisms either directly¹⁷, or by acting as substrates for myeloperoxidase-mediated halogenation¹⁸. We report here, however, that a major consequence of the defective function of this oxidase in neutrophils and monocytes from CGD patients is an absence of the normal initial rise, and an unusually rapid and extensive fall in pH which is itself associated with the impairment of the killing and digestion of intracellular staphylococci.

Phagocytosis and bacterial killing were measured in cells from five severely affected male patients with X-linked CGD, all of whose cells lacked spectral evidence of cytochrome *b*₂₄₅ (ref. 9), a mildly affected girl with the autosomal recessive variant⁹ and normal subjects. Phagocytosis was assayed by lysostaphin lysis of extracellular organisms¹⁹. It was very rapid in normal cells (*t*_{1/2} = 0.65 min) and maximal at 4 min (Fig. 1). The bacteria then re-emerged from the cells as shown by an increase in extracellular radioactivity from 13% at 4 min to 32% at 16 min. This expulsion of phagocytosed material, mostly in the form of particles which sedimented after gentle centrifugation, has been described previously²⁰. Phagocytosis by the patients' cells was slightly slower (*t*_{1/2} = 1.26 min), and there was no evidence of the subsequent release of bacteria from the cells (Fig. 1).

Bacterial killing by normal cells was very rapid (Fig. 1). The patients' cells also killed more than half the organisms and when corrections were made for extracellular organisms it was calculated that no bacteria remained viable within normal cells and that only 22% of those within the patients' cells survived.

To what can one attribute the reduced efficiency of bacterial killing by CGD cells? We have previously proposed that one role of the vacuolar cytochrome system is to regulate the pH within phagocytic vacuoles^{11,21}, and there is evidence that the pH falls faster after phagocytosis in CGD than in normal cells²². Thus, we measured early pH changes in the phagocytic vacuoles of leukocytes from healthy and granulomatous individuals, using the pH indicator fluorescein²³ conjugated to *Staphylococcus aureus*. Glass coverslips were coated with monolayers (1×10^4 cells mm⁻²) of neutrophils (>95% pure) and mononuclear cells (>80% monocytes) which were then exposed to a suspension of fluoresceinated bacteria at 4 °C. The pH of the bacterial environment was determined by measuring fluorescein emission

Fig. 1 Phagocytosis and killing of staphylococci by normal (●, ○) and CGD (×) neutrophils. Solid line, intracellular bacteria; broken line, viable bacteria (%). *S. aureus* (Oxford Strain NCTC 6571) from an overnight culture in broth (Oxoid) containing 25 μ Ci ml⁻¹ ³H-glucose (Radiochemical Centre, TRK. 85) were opsonized with human IgG (ref. 41) and added (in a 1:1 ratio) to 1×10^8 purified neutrophils (>95% in normals, patients' cells containing 5–10% eosinophils) in 1.5 ml RPMI 1640 medium (Flow Labs) containing 5 IU ml⁻¹ heparin in a rapidly stirred thermostatically controlled chamber⁴¹. Aliquots (50 μ l) were taken into 500 μ l ice-cold RPMI containing *N*-ethyl maleimide (1 mM) and 100 μ g ml⁻¹ lysostaphin (Sigma). The samples were mixed, incubated at 37 °C for 15 min, recooled and centrifuged at 7,000g for 4 min. Radioactivity in the supernatant was measured in a liquid scintillation counter. Fifty-microlitre aliquots of the mixture of bacteria and cells were taken at the same times into 10 ml ice cold H₂O. After 1 h aliquots were plated out for colony counts. Results are expressed as the mean $\pm$ s.e. of seven studies on cells from six CGD patients, each study being controlled with a simultaneous study on normal cells. Lactate dehydrogenase (mean $\pm$ s.e. of four experiments) release³⁰ from normal cells is shown (■).

at selected excitation wavelengths at various times after the initiation of phagocytosis. In normal neutrophils an increase in peak fluorescence corresponding to an apparent rise of intravacuolar pH to 7.75 was observed within the first 2 min (Fig. 2). Thereafter the pH fell slowly to 6.0–6.5 after 2 h. The same pattern was observed with normal monocytes (Fig. 2b). Similar studies with yeasts impregnated with the pH indicator bromothymol blue^{22,24} also showed that almost immediately following phagocytosis by normal cells there was a transient colour change from yellow to blue indicating a rise in pH from 6.8 in the medium to >7.6.

The pattern of pH changes with phagocytosis was clearly different in CGD leukocytes. There was neither colour change with bromothymol blue-impregnated yeasts, nor initial fluorescence increase with fluorescein-labelled *S. aureus*; instead the pH fell rapidly from 7.4 to 6.7 within 2 min. The final vacuolar pH of 5.5 was lower than that of normal cells. Addition of methylamine, which elevates the pH of secondary lysosomes²³, to the cell perfusate and the pre-incubation medium, effectively prevented this early rapid drop in vacuolar pH (Fig. 2), although phagocytosis was not inhibited.

Furthermore, spectra from fluorescent *S. aureus* bound to CGD or normal neutrophils at 10 °C (before phagocytosis) were identical to the spectrum of the free bacterium at pH 7.4, whereas after 13 min incubation at 37 °C the spectra were

completely different; that of CGD cells could be fitted best by the pH 5.9 spectrum of fluorescein and that of normal cells by the pH 7.0 spectrum (data not shown).

When the experiment was repeated with normal human neutrophils in anaerobic conditions, achieved by perfusing the cells with degassed buffers or mixing a concentrated suspension of neutrophils with the fluorescent bacteria at 4 °C in fine capil-

Fig. 2 Phagosomal pH in leukocytes after phagocytosis. *a*, Neutrophils: mean $\pm$ s.d. of two studies on each of two patients with CGD and one study on a third ($\blacktriangle$) and on five paired control subjects ($\bullet$). The effects of methylamine²³ (10 mM) on the pH within CGD cells ($\blacksquare$) and cytochalasin β ($1 \mu\text{g ml}^{-1}$) on control cells ($\circ$) are also shown. *b*, Monocytes: mean results of studies on two CGD patients ($\blacktriangle$) and paired control subjects ($\bullet$). *S. aureus* (50 μl of packed organisms) was well washed with saline and 50 mM pyridine-HCl buffer, pH 5.0. The bacteria were resuspended in 1 ml of the same buffer and mixed with 40 μl of fluorescein amine isomer I (Sigma), 1 mg ml^{-1} in dioxan. One mg of 1-ethyl 3-diaminopropyl carbodiimide was added and the suspension agitated for 2 h. The suspension was washed first in the pyridine buffer containing 100 mM glycine and then in saline. Fluorescence microscopy showed that the killed bacteria had been uniformly surface labelled. Freshly isolated human neutrophils or mononuclear cells⁴² were allowed to attach to acid-etched glass coverslips for 15 min at room temperature. Non-adherent cells were then washed away with RPMI medium, and the resulting monolayers were stored under this medium. Fluorescent *S. aureus* opsonized with IgG (ref. 41) were allowed to sediment on to leukocyte monolayers and attach at 4 °C for 20 min. Free or loosely bound labelled bacteria were removed by vigorous washing in ice-cold saline or RPMI medium. Fluorescence monitoring with a Perkin-Elmer MPF 4 fluorimeter began immediately after transfer of the cold monolayer to pre-warmed fluorescence cuvettes perfused with oxygenated RPMI medium at 37 °C. Phagosomal pH was calculated from the shape of the pH-dependent excitation spectrum of fluorescein by comparison with calibration spectra over a pH range of 4–8 from the same fluorescent bacteria adsorbed to glass in the absence of cells. The excitation spectra from fluorescent bacteria were corrected for the intrinsic fluorescence of the leukocytes and for scattered light.

larities which were then sealed, the initial pH rise was abolished and the pH fell rapidly, just as in the CGD patients' cells.

In these experiments bacteria were layered on the monolayers of cells at 4 °C to permit attachment without phagocytosis, which was then synchronized by rapid warming to 37 °C. To ensure that cooling the cells to 4 °C was not modifying the results, the cells were incubated with bacteria at 25 °C for 30 s before vigorous washing and pH measurement. The same pH changes as described above were observed in normal and CGD cells. Pre-incubation with cytochalasin B (5 μM) retarded phagocytosis and diminished and delayed the pH changes (Fig. 2). Neither the direct action of the products of the oxidase, generated at pH 7.4 with a xanthine oxidase-hypoxanthine system⁹, nor the method of coupling the fluorescein to the organism, on carboxyl groups with carbodiimide or on amino groups with isothiocyanate, altered the fluorescence characteristics of fluorescein.

The fluorescence measurements include signals from both phagocytosed bacteria and extracellular organisms which remain in the buffered medium. As the constant signal from the latter minimizes the average change, and consequently that attributable to intracellular particles, it was important to measure the phagocytosis of bacteria by the monolayer cells, which was done by the release of radioactivity from extracellular bacteria after digestion with lysostaphin as described in Fig. 1 legend. Fifty per cent were taken up by 30 s, 80% by 2 min and a maximum of 10% finally remained extracellular. The kinetics of phagocytosis were the same in cells from a patient with CGD. In studies with fluorescent *S. aureus* the addition of lysostaphin after 15 min caused a small decrease in fluorescence, but insufficient to alter the pH profiles, confirming that the pH measurement pertained to organisms within the cell.

To determine whether the excessively acid conditions within the vacuole of CGD cells could explain the defective bacterial killing, we examined the killing of staphylococci by the cells of two patients in the presence and absence of 10 mM methylamine, which we had shown to elevate the pH in the vacuoles of patients' cells (Fig. 2). Regression analysis of the relationship between extracellular and viable organisms (see Fig. 1 legend) indicated that in the presence of methylamine (which did not itself kill bacteria) all the intracellular organisms were killed and that bacterial killing was significantly better ($P < 0.02$)²⁵ than in its absence.

To investigate other possible effects of the excessive acidity in CGD vacuoles we measured the digestion of radiolabelled, heat-killed staphylococci. Solubilization of the phenylalanine label was less than half of normal, that of the incorporated glucose was about 80% of normal whereas that of uridine label was normal (Fig. 3). Phagocytosis of the labelled bacteria by the two groups of cells was similar. The differences in the solubilization of bacteria seemed unrelated to differences in their content of hydrolytic enzymes because incubation of labelled bacteria with homogenates of normal or CGD cells at pHs of 5–8 released similar amounts of radiolabelled phenylalanine and glucose. Nor could the reduced solubilization in CGD cells be accounted for by less efficient degranulation. Phagocytic vacuoles, isolated by flotation²⁶, from four patients were in fact found to contain more enzymes than normal, the specific activities of β glucuronidase²⁷, lysozyme²⁸ and myeloperoxidase²⁹ being 4.55, 2.86 and 1.19 of those in vacuoles from the paired control cells. Half-maximal degranulation times for these enzymes, determined over 1 h, were normal²⁶.

We next investigated the difference between the expulsion of phagocytosed bacteria by normal and CGD cells (Fig. 1). We found that normal cells released three times more solubilized ³H-glucose label than cells of the four patients (Fig. 3a, $P < 0.0025$)²⁵, although cell damage as measured by lactate dehydrogenase release³⁰ after incubation for 2 h was not significantly different (5.7 ± 1.2 (s.e.) in controls and $8.0 \pm 3.9\%$ in patients). For morphological studies cells and bacteria were incubated in the conditions used in the killing assay (see Fig. 1 legend) and timed samples were collected for electron

Fig. 3 Solubilization of heat-killed radiolabelled staphylococci by, and release of solubilized radioactivity from, CGD and normal neutrophils. Bacteria were grown in broth containing ^3H -glucose ($25 \mu\text{Ci ml}^{-1}$), ^3H -uridine ($1 \mu\text{Ci ml}^{-1}$) or ^{14}C -phenylalanine ($0.2 \mu\text{Ci ml}^{-1}$) (Radiochemical Centre) and then washed, killed by heating in a boiling water bath for 10 min, rewashed and opsonized with IgG⁴¹. Radiolabelled bacteria were mixed with cells (1:1) and rapidly shaken at 37°C . Solubilization was measured by lysing the cells with distilled water, centrifuging at $8,000g$ for 10 min, homogenizing the pellet in distilled water recentrifuging and counting the radioactivity in the supernatants. Release of solubilized radioactivity was examined by centrifuging the cells and bacteria at $7,000g$ for 1 min after various incubation times, and determining the radioactivity in the supernatant. *a*, Solubilization of uridine (mean of two patients, $\blacksquare$, and controls, $\square$) and glucose (mean $\pm$ s.e. of four patients, $\bullet$, and controls, $\circ$) and release of the solubilized ^3H -glucose label (mean $\pm$ s.e. of four patients, $\star$, and controls, $\star$). *b*, Solubilization of ^{14}C -phenylalanine by cells from two patients ($\blacktriangle$) and controls ($\triangle$). Methylamine (10 mM) enhanced solubilization by both the CGD ($\blacktriangledown$) and control ($\times$) cells.

microscopic examination. After about 2 min the vacuoles in normal, but not in CGD, cells began to swell and became much larger than the enclosed bacterium (Fig. 4). The mean vacuolar volume in normal cells, as calculated from the cross-sectional area of vacuoles on electron micrographs, was approximately $15 \mu\text{m}^3$ after 8 min and $22 \mu\text{m}^3$ after 16 min, in comparison with 4.0 and $4.5 \mu\text{m}^3$ in the patients' cells after the same incubation times (see Fig. 4 legend).

The abnormally small size of phagocytic vacuoles in CGD^{8,31} has been attributed to a reduction in the release of granule contents into the vacuole as a result of defective degranulation. However, as described here and by others³², degranulation is not defective in CGD and although the enlarged vacuoles seen in normal cells appear swollen, they are not obviously distended with electron-dense granule contents. We propose instead that phagocytic vacuoles in normal cells enlarge as a result of the attraction of water by osmotically active digestion products of

the ingested bacteria, and that the vacuoles in CGD cells are much smaller because, as shown in Fig. 3, digestion within their vacuoles is impaired. This hypothesis is supported by our findings that even after incubation times as long as 1 h there is virtually no swelling of vacuoles by normal cells after the phagocytosis of indigestible latex particles opsonized with the same IgG as the bacteria, and that in the presence of methylamine, which enhances bacterial digestion, the mean volume of the patients' vacuoles increased from a calculated 4.5 to $15 \mu\text{m}^3$ ($P < 0.005$, see Fig. 4 legend).

We suggest that the normal sequence of events following phagocytosis of staphylococci is as follows. After entry of the bacteria, the vacuole oxidase system elevates the intravacuolar pH via a cytochrome b_{-245} mediated⁹⁻¹¹ transport of electrons from the cytosolic to the luminal surface. The resultant reduction of molecular oxygen to O_2^{2-} would consume protons during the formation of H_2O_2 (refs 13, 14), raising the intravacuolar pH. The raised pH facilitates killing and bacteriolysis by granule proteins³³⁻³⁶ following which the pH of the vacuoles is reduced to optimize the activities of hydrolases and other proteins with acid pH optima³⁷. In normal vacuoles the generation of low-molecular-weight hydrolysis products is evidently sufficiently rapid to swell osmotically the vacuoles containing the disintegrating organisms. The vacuole enlarges until it comes into contact and fuses with the plasma membrane, releasing the partially digested bacterium and solubilized products, possibly with immunogenic potential, into the extracellular environment. In CGD, however, the absence of the oxidase results in a rapid fall in vacuolar pH inhibiting the killing mechanisms, although not before they have disposed of most of the ingested organisms, and impairing subsequent microbial digestion and its effects on vacuolar morphology. Impaired digestion could account for the lipochromic material that accumulates within histiocytes in the tissues of these patients^{38,39}.

Differences in the control of the pH of endocytic vacuoles might be one of the factors responsible for variations in the susceptibility of individuals to infection and could be manipulated therapeutically⁴⁰.

Fig. 4 Transmission electron micrographs of neutrophils from *a*, a normal subject, and *b*, a male patient with CGD ($\times 5,600$). Samples were fixed and processed 16 min after exposure to opsonized staphylococci. Phagocytic vacuoles in normal cells were found to be enlarged and to contain bacterial debris whereas those in CGD cells were much smaller and the bacteria appeared undegraded. Prints were made of electron micrographs of 10 randomly selected cells at each time interval and between 20 and 40 phagocytic vacuoles containing bacteria that appeared to have been sectioned through their region of maximum diameter were excised and weighed. The samples were coded and only identified after the conclusion of the measurements. Cross-sectional areas were determined by comparing the weights of excised vacuoles with those of intact bacteria (radius $\sim 0.6 \mu\text{m}$)⁴³. The cross-sectional areas of the patients' vacuoles were significantly smaller than those of the control (2.8 ± 0.2 and 2.9 ± 0.2 compared with 6.5 ± 1.2 and 8.3 ± 1.0 times that of the bacteria at 8 and 16 min respectively, $P < 0.005$ and $P < 0.001$)²⁵. The cells of another patient were examined and although not quantified, the vacuoles were also obviously much smaller than those in the paired control cells.

We thank the Wellcome Trust and MRC for financial support, Drs David Fellingham and Richard Whitton for helpful advice, and Professors D. Weatherall and M. Greaves for allowing us to study patients under their care.

Deficiency in cells expressing terminal transferase in autoimmune (motheaten) mice

Kenneth S. Landreth*, Kathleen McCoy†, James Claggett‡, F. J. Bollum§ & Cornelius Rosse*

Departments of *Biological Structure, †Microbiology/Immunology, and ‡Periodontics and Microbiology/Immunology, University of Washington School of Medicine, Seattle, Washington 98195, USA
§Department of Biochemistry, Uniformed Services University of the Health Sciences, Bethesda, Maryland 20014, USA

The extensive breakdown of immune homeostasis in the motheaten mouse (*me/me*) has been ascribed to a single gene defect on chromosome 6 (ref. 1). These mice develop skin lesions within the first week of life, do not thrive, and die within the first 3–8 weeks². There is severe hypergamma-globulinaemia³ with multiple species of circulating autoantibody^{3–5} and deposition of immune complexes in the thymus, skin, lungs and kidneys^{1,3}. A single gene defect producing such catastrophic results may provide an important model for understanding autoimmune phenomena. We report here a virtual absence of terminal deoxynucleotidyl transferase-positive (TdT⁺) cells in the bone marrow, thymus and spleen of motheaten mice. TdT is a DNA polymerase which has the unique capacity to polymerize nucleotides in the absence of template direction⁶. Although no *in vivo* biological function of this enzyme has been established, its unique appearance in the bone marrow and thymus of adult mammals and its *in vitro* biochemical activity⁶ have led to a proposed role for TdT in the somatic diversification of lymphocytes⁷. Bone marrow TdT⁺ cells have been shown to belong to both T⁸ and B^{9,10} cell populations and may also include precursor cells common to these lineages¹¹. Although the role of TdT in the acquisition of appropriate T- and B-cell specificities is not known, our results are the first to correlate the virtual absence of TdT⁺ cells with a severe autoimmune syndrome. We investigated the level of TdT⁺ cells in neonatal *me/me* mice and their normal littermates and the susceptibility of TdT⁺ cells to circulating autoantibody in motheaten mouse serum.

Bone marrow, thymus and spleen cells obtained from 21–25-day-old C3HeB/FeJ *me/me* mice, their normal littermates and C3HeB/FeJ wild-type mice were stained for TdT with immunoadsorbent-purified rabbit anti-calf TdT, previously shown to have good cross-reactivity with mouse TdT¹². The

TdT-specific reagent was visualized with fluorescein isothiocyanate (FITC)-conjugated F(ab')₂ goat anti-rabbit IgG. We found an extremely low incidence of TdT⁺ cells in both bone marrow and thymus of *me/me* mice compared with normal littermates and wild-type mice (Table 1). Most of the motheaten mice examined had no TdT⁺ cells, but when present, the numbers of these cells seemed to be inversely correlated with the severity of disease as judged by body weight and skin lesions (unpublished data).

As *me/me* mice possess circulating IgM autoantibodies to thymocytes^{1,5,13}, we tested whether or not motheaten mouse serum had autoantibody to TdT⁺ cells in the lymphoid tissues. Serum was collected from 10 *me/me* mice and 10 normal littermates between 21–25-days old, and incubated with C3HeB/FeJ wild-type bone marrow and thymus cells (Table 2). The binding of *me/me* serum IgM to normal bone marrow and thymus cells was visualized with tetramethylrhodamine isothiocyanate (TRITC)-conjugated specific goat anti-mouse μ (ref. 14) and TdT was stained as already described. As shown in

Fig. 1 The incidence of TdT⁺ cells in the thymus (a) and bone marrow (b) of *me/me* mice (Δ) and their normal littermates (○). Cells were collected and stained as described in Table 1. Over 1,000 cells were counted in cytocentrifuge preparations from each of five individual mice; values plotted are mean ± s.d.

† Present address: Sloan-Kettering Institute for Cancer Research, 145 Boston Post Road, Rye, New York 10580, USA.

Table 2, motheaten mice possess circulating IgM autoantibodies that bind to $64.28 \pm 10.37\%$ of normal thymocytes and to $15.38 \pm 7.54\%$ of bone marrow cells; IgM in normal littermate serum samples did not bind to any cells. In the thymus, most of the cells that bound *me/me* autoantibody were also TdT⁺, in contrast to the bone marrow, where none of the cells that bound autoantibody were TdT⁺.

The virtual absence of TdT⁺ cells in the thymus of *me/me* mice in the terminal stages of the autoimmune disease may be due to cytolysis by circulating autoantibody. In the thymus of normal littermates, $56.2 \pm 2.5\%$ of cells were TdT⁺ by 7 days of age and the incidence of these cells remained almost constant up to day 21 (Fig. 1; compare with ref. 6, Fig. 1), but in *me/me* mice only $19.6 \pm 6.8\%$ of thymus cells were TdT⁺ at 7 days. By day 12 the incidence of TdT⁺ cells in the thymus of *me/me* mice had fallen to $0.45 \pm 0.19\%$ and remained at this barely detectable level up to day 21. In normal littermates $3.89 \pm 1.01\%$ of bone marrow cells were TdT⁺ at day 7, increased to $5.91 \pm 0.67\%$ by day 12 and remained at $4.42 \pm 2.10\%$ on day 21. In *me/me* mouse bone marrow only 0.54 ± 0.45 – $0.76 \pm 0.75\%$ of nucleated cells were TdT⁺ at all time points of observation.

One explanation for the virtual absence of TdT⁺ cells in the thymus of motheaten mice by the age of 3 weeks could be autoimmunolysis of TdT⁺ thymocytes—such cell death would be consistent with the decrease in total thymic cellularity during the first 3 weeks¹. Our data suggest that the primary targets for the autoantibody are the TdT⁺ thymocytes found in the thymus cortex¹². Unlike the thymus, the number of TdT⁺ cells in motheaten marrow was low throughout the observation period. Because no binding of autoantibody to TdT⁺ cells could be demonstrated in the bone marrow of 21–25-day-old wild-type mice, it is difficult to attribute the absence of TdT⁺ cells in the marrow to autoimmunolysis. There are four possible explanations for this: (1) cells in defective bone marrow produce a variant of TdT not recognized by our antibody; (2) TdT⁺ cells

Table 1 Incidence of TdT-positive cells in the thymus, bone marrow and spleen of motheaten and normal mice

	% TdT ⁺ cells		
	Thymus	Bone marrow	Spleen
Wild type	52.50 ± 12.34	3.66 ± 1.49	0.12 ± 0.27
Normal littermates	54.25 ± 19.99	4.21 ± 2.08	4.66 ± 2.13
Motheaten	1.43 ± 1.89	0.72 ± 0.81	0.61 ± 0.54

Motheaten mice on a C3HeB/FeJ background, normal littermates and wild-type C3HeB/FeJ mice (obtained from our own breeding colony or from Jackson Laboratories) were killed by cervical dislocation, the femora removed and the contents flushed at 4°C with Hanks' balanced salt solution (HBSS, Microbiological Associates) which contained 5% heat-inactivated fetal calf serum (FCS, Microbiological Associates) and 0.08% NaN₃. Spleens were placed in HBSS at room temperature and teased to extrude cells. Thymic lobes were minced in cold HBSS. Single cell suspensions of each tissue (>90% viable as assessed by trypan blue exclusion) were washed twice in HBSS. An equal volume of 2% paraformaldehyde in phosphate-buffered saline (PBS, pH 7.2) was added to 1.5 – 2.0×10^6 bone marrow, spleen and thymus cells in 0.25 ml HBSS. The cell suspension was kept on ice for 15 min followed by cytocentrifugation (Shandon Scientific) on to clean glass slides at 500 r.p.m. for 3 min. Slide preparations were air dried and immediately fixed in absolute methanol for 20 min at 4°C, then rehydrated through three changes of PBS containing 0.05% NaN₃ at 4°C and dried, excluding the area of the fixed cells which remained wet throughout the staining procedure. Monospecific rabbit anti-TdT (10 µl, Lot A02; 30 µg ml⁻¹ antibody, 100 µg ml⁻¹ BSA) was applied and incubated for 30 min at room temperature in a humidified chamber. Slides were washed three times in excess PBS and incubated a second time with 10 µl of FITC-F(ab')₂ anti-rabbit IgG (10 µg ml⁻¹ in PBS with 100 µg ml⁻¹ of BSA). Slides were finally washed in excess PBS (0.05% NaN₃) for 6–10 h, mounted in Tris-buffered glycerol, pH 9.5, and counted on a Leitz Ortholux epifluorescent microscope. Over 1,000 consecutive cells were counted from each of five individual mice; values are mean $\pm$ s.d.

Table 2 Percentage of bone marrow and thymus cells of wild-type C3HeB/FeJ mice that bind autoantibodies

	Normal littermate serum ⁺	<i>me/me</i> serum ⁺	<i>me/me</i> serum ⁺ and TdT ⁺
Bone marrow	0	15.38 ± 7.54	0
Thymus	0	64.28 ± 10.37	52.50 ± 17.3

To assay circulating autoantibodies in *me/me* mice, bone marrow and thymus cells from wild-type C3HeB/FeJ mice were first incubated with intact or F(ab')₂ goat anti-mouse μ specific antibody for 30 min on ice to block μ determinants on the cell surface. Cells were then washed three times in HBSS (5% FCS, 0.08% NaN₃). Blocking efficiency was checked by incubation of these cell samples with TRITC-conjugated F(ab')₂ goat anti-mouse μ ¹⁴ for 30 min on ice followed by two washes of the cells with HBSS. This procedure routinely reduced detection of μ ⁺ cells to <0.5% in the marrow. One aliquot of the cell samples was mixed with normal mouse serum (diluted 1:5 in HBSS) and another aliquot with *me/me* mouse serum (diluted 1:5 in HBSS) and both were incubated for 30 min on ice. Both cell aliquots were then washed twice in HBSS followed by incubation with TRITC-F(ab')₂ goat anti-mouse μ as described. Washed cell aliquots were fixed in paraformaldehyde as described in Table 1 legend, cytocentrifuged on to clean glass slides and stained for TdT (see Table 1). Cell preparations were mounted in Tris-buffered glycerol, pH 7.0, and counted on a Leitz Ortholux epifluorescent microscope with appropriate filtration for scoring of both FITC-labelled TdT and TRITC-labelled IgM autoantibodies on the same slide. Cell counts represent >1,000 cells counted for each of 10 preparations; mean $\pm$ s.d.

are normally thymus derived; (3) TdT⁺ cells are rapidly exported from motheaten marrow to the involuting thymus or (4) there is a defective production of TdT⁺ bone marrow cells in these mutant mice. The first of these explanations seems unlikely because it requires postulating a species of TdT in *me/me* bone marrow that is antigenically distinct from TdT in *me/me* thymus or from that in normal mouse bone marrow and thymus cells. The post-thymic origin of TdT⁺ bone marrow cells is also considered unlikely because such cells are present in normal numbers in nude mouse bone marrow¹⁵. Present data do not allow a choice between the rapid export and deficient production of TdT⁺ cells. However, even if the paucity of TdT⁺ cells in the bone marrow is due to accelerated migration to the thymus, this explanation would not account for the absence of those TdT⁺ cells in the marrow which are committed to the B-cell lineage, because such cells are unlikely to migrate to the thymus.

The gross abnormality in immunoglobulin production that characterizes the *me/me* syndrome may well be linked to the defect in TdT⁺ B-lineage cells, whereas other manifestations of the *me/me* syndrome may depend on defects in TdT⁺ T cells of both bone marrow and thymic origin. Defective production of TdT or of TdT⁺ cells in the *me/me* mouse may provide important clues about autoimmunity and the normal biological function of TdT. If the enzyme does play a part in the somatic diversification of the molecules by which lymphocytes recognize antigen, then a failure in its production in the developing cell lineage might result in severely decreased heterogeneity of those molecules and in the antigen recognition capacity of the *me/me* mouse. Twenty-one-day-old *me/me* mice fail to respond to foreign antigenic stimulation by either specific antibody production^{3,13,16} or the generation of cytotoxic killer cells¹⁶, yet they exhibit hypergammaglobulinaemia^{1,3,16} and normal numbers of peripheral T cells^{1,5,16}. Preliminary data from our laboratory show that serum immunoglobulins from *me/me* mice have a lower heterogeneity than immunoglobulin from normal littermate serum analysed on two-dimensional polyacrylamide gels after immunoprecipitation of radiolabelled immunoglobulins (D. Putnam, K. McCoy, A. Jones and J. Claggett, unpublished data). These results strengthen the hypothesis that the underlying cause of motheaten pathology may, in part, result from a defect in the production of TdT.

It is intriguing to speculate that a failure in production of TdT⁺ lymphoid precursor cells may be an important defect in autoimmune disease, but other animal models of immune dysfunction need to be examined for changes in TdT-bearing cell populations during the progression of disease. Immunodeficient nude mice have near normal bone marrow TdT⁺ populations that develop early in neonatal life¹⁷ in the virtual absence of TdT⁺ thymocytes. The *nu/nu* mouse defect is primarily related to T cells whereas the *me/me* mutation affects both T and B functions.

The tumour promoter 12-*O*-tetradecanoyl-phorbol-13-acetate (TPA) and structurally related phorbol esters effect changes in avian and mammalian cell cultures that mimic transformation by oncogenic viruses or chemical carcinogens and the inhibition or induction of various types of differentiation (for review see refs 1–3). Unlike initiating carcinogens, which seem to act by binding covalently to cellular DNA, the primary site of action of the phorbol ester tumour promoters seems to be the cell membrane^{2,3}; indeed, specific high-affinity saturable receptors for phorbol esters have been identified in cell membranes^{4,5}. The recently discovered class of tumour promoters, the teleocidins⁶, are as potent as TPA in the induction of ornithine decarboxylase in mouse skin, the inhibition of differentiation of Friend erythroleukaemia cells, the induction of HL-60 cell adhesion⁶ and the promotion of tumours on mouse skin⁷. As the teleocidins are structurally unrelated to the phorbol esters, we set out to determine their effects on cell membranes and receptors. We found that in rodent cell cultures, teleocidin B and dihydroteleocidin B have effects similar to those of TPA and that, at nanomolar concentrations, teleocidin inhibits the binding of phorbol esters to cell-surface receptors, which suggests that the action of both classes of compounds may be mediated by the same or a similar receptor system.

TPA enhances the transformation of the mouse embryo cell line C3H 10T1/2 cells on first exposure to radiation or chemical carcinogens^{8–10}. It was of interest, therefore, to see if TPA and the teleocidins exert similar biochemical effects in these cells.

An early membrane response to TPA in mouse skin and certain cell cultures is induction of arachidonic acid release from membrane phospholipids, associated with the synthesis of the arachidonic acid products prostaglandin E₁ and F_{2α} (refs 11–13). In Fig. 1, C3H 10T1/2 cells were prelabelled with ³H-arachidonic acid in conditions in which >95% of the acid is incorporated in phospholipids¹². The subsequent addition of TPA, teleocidin B or dihydroteleocidin B (100 ng ml⁻¹) to these cultures led to the rapid release of ³H-arachidonic acid into the media (Fig. 1a), reflecting increased phospholipid degradation. As with TPA, the teleocidin-induced release of arachidonic acid was also associated with increased synthesis of prostaglandins E₁ and F_{2α} (data not shown here). Concentration curve studies indicated that the optimum concentrations of teleocidin B and dihydroteleocidin B were ~10 ng ml⁻¹ and that these agents were actually more potent than TPA in inducing arachidonic acid release (Fig. 1b). The exposure of avian and mammalian cells to TPA causes a rapid enhancement in the uptake of 2-deoxyglucose^{14,15} and certain other nutrients^{2,3}; we found that teleocidin B and dihydroteleocidin B stimulated 2-deoxyglucose uptake by C3H 10T1/2 cells to levels comparable with those obtained for TPA when all three agents were tested at 100 ng ml⁻¹ concentrations (data not shown).

An additional early and specific response of cells to TPA is inhibition of binding of epidermal growth factor (EGF) to its cell-surface receptors^{16–19}. Although this does not seem to be due to direct binding of TPA to the receptor^{17–19}, it does provide a highly sensitive marker of membrane changes induced by the

Fig. 1 Arachidonic acid and prostaglandin release were assayed as described elsewhere. Phospholipids of C3H 10T1/2 cells were prelabelled by incubation of 4×10^5 cells per plate with 1.25 μ Ci per ml of ³H-arachidonic acid (62.2 Ci mmol⁻¹, NEN) for 24 h. The prelabelled cells were then washed and incubated in 2 ml of serum-free Dulbecco's minimal essential medium (DMEM) containing either solvent or the indicated chemicals at 37 °C. At the indicated times the media were removed, acidified and extracted with ether. After evaporation of the ether, the sample was solubilized in 0.2 ml of chloroform. A portion (0.04 ml) was applied to silica gel TLC plates with nonradioactive markers, developed in 2,6-dimethylheptanone/glacial acetic acid/0.9% NaCl (80:40:6), and the plate scraped and assayed for radioactivity. Values are means of duplicate samples which agreed within 10%. Two additional experiments gave similar results. *a*, Samples were incubated with 30 ng per ml of TPA (▲), teleocidin B (●), dihydroteleocidin B (□), or the dimethyl sulphoxide (DMSO) solvent (○) for the times indicated. *b*, Samples were incubated with the indicated concentrations of TPA (▲), teleocidin B (●), dihydroteleocidin B (□), or DMSO (○) for 1 h at 37 °C. With the DMSO solvent control there was negligible release of radioactivity, presumably because spontaneous phospholipid turnover is reduced in the serum-free incubation system (ref. 12 and unpublished results).

Fig. 2 Inhibition of EGF binding: 2×10^6 C3H 10T1/2 cells were incubated with 0.05 μ Ci (0.2 ng) of ^{125} I-EGF (120 mCi per mg, Collaborative Research) in 2 ml of serum-free DMEM with the indicated concentration of TPA ($\blacktriangle$), teleocidin B ($\bullet$), or dihydroteleocidin B ($\square$) for 2 h, washed and assayed for cell-bound radioactivity as described elsewhere¹⁷. The control value was 940 c.p.m. per dish and is expressed as 100%. Values are means of duplicate samples which agreed within 10%. Two additional experiments gave similar results.

phorbol ester tumour promoters. Figure 2 indicates that the addition of 0.1–10 ng ml^{-1} of TPA, teleocidin B or dihydroteleocidin B simultaneously with the addition of ^{125} I-EGF led to a marked inhibition of ^{125} I-EGF binding to C3H 10T1/2 cells. All three compounds also inhibited ^{125} I-EGF binding in a line of rat embryo cells (FRE-8D) and in HeLa cells (data not shown). In C3H 10T1/2 and FRE-8D cells, TPA was rather more potent than the teleocidins in inhibiting ^{125} I-EGF binding whereas the three compounds had similar potencies for HeLa cultures.

Several aspects of the action of the phorbol esters have led to the suggestion that they act by usurping cell membrane receptors normally occupied by an endogenous growth factor^{1,16}. Using ^3H -phorbol-12,13-dibutyrate (PDBu) to avoid non-specific binding, Blumberg⁴ has in fact recently demonstrated that membrane fractions from avian and mouse cells contain saturable high-affinity receptors for this compound. A modification of this approach has also demonstrated receptors for ^3H -PDBu on intact monolayers of rat embryo fibroblasts and several other cell types⁵. Figure 3 shows that at 37 °C, concentrations of teleocidin B in the range 0.5–10 ng ml^{-1} were able to produce marked inhibition of the specific binding of ^3H -PDBu to rat embryo fibroblast monolayer cultures; 50% inhibition was achieved with $\sim 2.5 \text{ ng ml}^{-1}$, which is equivalent to about 10^{-9} M . Teleocidin was more potent than TPA in inhibiting ^3H -PDBu binding, because $\sim 3.8 \text{ ng ml}^{-1}$ of TPA were required to produce 50% inhibition (Fig. 3). The ID_{50} value for PDBu was 23 ng ml^{-1} (data not shown). No inhibition was observed with as much as 1,000 ng ml^{-1} of phorbol, which lacks tumour promoting activity, nor was inhibition obtained with EGF, presumably because it occupies separate receptors^{4,5,17}. In additional studies (not reported here) of ^3H -PDBu binding, carried out at 4 °C rather than 37 °C, teleocidin B was also a more potent inhibitor than TPA. Thus, in contrast to the TPA inhibition of EGF binding^{17–19}, teleocidin B inhibition is not highly temperature dependent. These results provide further evidence that teleocidin B competes directly with ^3H -PDBu for receptor binding.

There is evidence that the TPA induction of arachidonic acid release, TPA enhancement of 2-deoxyglucose uptake and TPA inhibition of EGF-receptor binding are direct membrane effects that do not require *de novo* RNA synthesis^{2,11,12,17}. Because of their similar time courses we would assume that this is also true

for the effects of teleocidin on these membrane-related properties. These results, together with our evidence that teleocidin B is a potent and apparently direct inhibitor of the binding of PDBu to its cell-surface receptors, suggest that the teleocidins might act as tumour promoters and induce changes in cell culture by binding to the same membrane-associated receptors as those used by TPA.

We emphasize that although teleocidin B was about 10 times more potent than TPA in inducing arachidonic acid release (Fig. 1) and slightly more potent in inhibiting ^3H -PDBu binding (Fig. 3), it was slightly less potent than TPA in inhibiting EGF-receptor binding (Fig. 2). Because these parameters are quite different and were not all assayed with the same cell cultures, the significance of these quantitative differences is unknown. It is possible that they reflect the existence of subtypes of ^3H -PDBu receptors⁵ that control different cellular effects, but this requires further study.

Teleocidin has an entirely different chemical structure from that of TPA or any of the TPA-related plant diterpenes, but both compounds are somewhat amphipathic. Teleocidin has a peptide-like moiety joined to a lipid portion containing two isoprenes⁶, while TPA contains a somewhat hydrophilic-substituted ring system and a long-chain lipophilic fatty acid residue³. These aspects may provide clues to the molecular details by which the two different classes of compound apparently bind to the same or a similar set of membrane receptors. In addition, the fact that two structurally diverse compounds with potent tumour promoting activity seem to bind to the same cell-surface receptors suggests that these receptors play a part in mediating the biological effects of the compounds.

We thank Drs R. A. Mufson and P. B. Fisher for their advice and Dr M. Takashima for providing dihydroteleocidin B. This research was supported by NCI grant CA-26056, DHEW, an

Fig. 3 Inhibition of specific binding of ^3H -PDBu. Rat embryo fibroblast cells (FRE-8D) were grown in 6-cm dishes containing DMEM plus 10% calf serum. The assay was performed on 2×10^6 cells per dish. The cell monolayer was washed once with phosphate-buffered saline (PBS) and then 2 ml of assay buffer (2 volumes DMEM/1 volume PBS, plus 1 mg ml^{-1} bovine serum albumin) were added. The indicated concentrations of teleocidin B ($\bullet$), TPA ($\blacktriangle$) or phorbol ($\triangle$) were added, followed by ^3H -PDBu (6.4 Ci mmol^{-1} , Lifesystems) to a final concentration of 3 nM. The cells were incubated for 30 min at 37 °C to achieve plateau binding, washed 3 times with assay buffer at 0 °C, solubilized in 1 ml of 0.8% Triton X-100, 0.02% EDTA and 0.25% trypsin in PBS, and assayed for radioactivity. Nonspecific ^3H -PDBu binding was assumed to be that obtained in the presence of 50 μM unlabelled PDBu. This value was $\sim 20\%$ of the total binding obtained in the absence of excess PDBu and was subtracted from all experimental data to obtain the values for specific saturable binding. Specific binding of ^3H -PDBu in the control assays was ~ 750 c.p.m. per 10^6 cells (equivalent to $\sim 1.1 \times 10^5$ receptors per cell), with a s.e.m. of $<10\%$. This control value is expressed as 100%. Similar results were obtained in two additional experiments. Further details of this assay will be published elsewhere⁵.

Synaptic facilitation requires paired activation of convergent pathways in the neocortex

A. Baranyi & O. Fehér

Department of Comparative Physiology, Attila József University of Sciences, Közpétfasor 52, Szeged 6726, Hungary

In associative learning, the activated neurones undergo a variety of concomitant functional alterations—increases or decreases of firing activity^{1–4} and modifications of membrane potential or resistance^{5–8} and of synaptic responsiveness^{9–11}. Synaptic transmission which can be strengthened only when there is paired activity in two pathways is of particular interest in relation to mechanisms for associative learning^{12,13}. For the neocortex, there are few observations of the plastic changes, induced by conditioning procedures, in the effectiveness of individual synapses^{14–17}. We now report that various regimes with joint stimulations of convergent excitatory pathways on to intracellularly recorded neurones in the motor cortex of the cat result in synaptic facilitation lasting for up to 30 min.

The experiments were performed on the exposed motor cortex of cats anaesthetized with 35 mg per kg Nembutal using conventional intracellular recording techniques. The surgical procedure, methods of stimulation and recording are reported elsewhere in detail^{15,16}. Synaptic responses were elicited by stimulation of the pyramidal tract, the ventrolateral thalamic nucleus (VL), the homotopic cortical surface (callosal stimuli) and the contralateral radial nerve (somatosensory activation). The membrane input resistance, R_m , was measured by the bridge-balancing method¹⁸. At least two excitatory synaptic inputs on to the intracellularly recorded cell were stimulated: one (test pathway) elicited only mono- or oligosynaptic excitatory postsynaptic potentials (test e.p.s.ps), while the other caused the cell to produce spike potentials (unconditioned stimulus, US) (Fig. 1a). Based on the cellular analogues of classical conditioning^{9,19} the applied conditioning paradigm consisted of (1) habituation, (2) pseudoconditioning, (3) conditioning, and (4) extinction procedures (Fig. 1b). A neurone was regarded as conditionable if the test e.p.s.p. was enhanced in

Fig. 1 a, Schematic drawing of the experimental arrangement used for cellular conditioning of neurones in the motor cortex. The stimulation of the test pathway produced an e.p.s.p. while stronger stimuli via another pathway elicited spike potentials in the recorded neurone. b, Illustration of the experimental paradigm. During the habituation procedure 150 test e.p.s.ps (H_1) and then 150 US spikes (H_2) were evoked from the respective inputs at a stimulus frequency of 0.2–1 Hz. Pc, pseudoconditioning procedure when test e.p.s.ps and US spikes were randomized with 0.2–1 Hz frequency within a block of 150 stimuli. C, conditioning procedure with e.p.s.p.–spike stimulus pairs at constant inter-stimulus interval ranging from 0 to 100 ms. E, extinction period when only test stimuli were given at 0.2–1 Hz until the augmented neuronal responses returned to the preconditioning level.

amplitude or in efficacy in evoking spike potentials by the conditioning procedure and if these changes were abolished by the extinction procedure.

In 38 cells (26% of the neurones tested) the efficacy of the test e.p.s.ps was enhanced after 60–90 stimulus pairings and the facilitated synaptic response persisted for periods from 3 to 41 min (mean $\pm$ s.d. 14.5 ± 9.5 min, $n = 38$). Figure 2 shows an example of synaptic facilitation by VL e.p.s.p.–callosal spike repetitive stimulus pairs. In other neurones e.p.s.p.–spike and spike–e.p.s.p. sequences were equally efficient, but only in stimulus pairs with inter-stimulus intervals of <40–60 ms in the former and ~ 100 ms in the latter. Inter-stimulus intervals above 100 ms (periods ranging from 100 to 500 ms were tested) proved ineffective in causing synaptic facilitation. This may be explained by supposing that both US spikes and test e.p.s.ps have an after-effect of about 100 ms in duration and their repetitive overlap is necessary for the facilitatory interaction between them. On the other hand, it could be demonstrated that the observed synaptic facilitation was specific to the pairing procedure, as repeated but unpaired presentation of test e.p.s.ps and US spikes during pseudoconditioning procedures never led to plastic changes (tested in 17 cases, Fig. 2b), and when a previously efficient e.p.s.p.–spike stimulus pair was applied together with a hyperpolarizing current pulse through the recording electrode (when spike generation by US stimuli was prevented), the test e.p.s.p. was not augmented (tested in 13 cases). The amount of hyperpolarization required to prevent action potentials by US stimuli during conditioning was sufficient to abolish the plastic after-effect. Based on the presented data, one may conclude that contingent pairing of the test e.p.s.ps with spike potentials, that is, temporal contiguity of pre- and postsynaptic excitations, is indispensable for the synaptic facilitation, as postulated previously^{20,21}.

Transient facilitations of the test e.p.s.ps lasting for 6–40 s were observed in all 17 neurones with which spike trains of 5–50 Hz frequency and 5–15 s duration were applied as US. This after-effect did not require co-active stimulation of the test and US pathways, because it also occurred when US stimuli were applied on their own. These short-lived effects presumably originated from transient modifications of the ionic micro-environment caused by frequent firing activity^{22–24}. In hippocampal neurones long-term facilitation of both e.p.s.ps and inhibitory postsynaptic potentials has been demonstrated as a

result of repetitive activation with similar parameters^{25,26}. In the motor cortex a considerably higher frequency and longer period of repetitive activation is necessary for long-term facilitation²⁷.

Enhancement of the amplitude of paired test e.p.s.ps was the only consequence of paired conditioning procedures in 21 cells, whereas in the other 17 neurones the synaptic facilitation was accompanied by 3–6 mV membrane depolarization and increases of R_m (Fig. 3). The depolarization presumably did not contribute to the augmentation of the test e.p.s.ps, as a test e.p.s.p. induced during a depolarizing current injection (causing 2–6 mV depolarization) was found in 11 tested cells to be decreased in amplitude or unaffected.

Fig. 2 Facilitation of a test e.p.s.p. by stimulus pairs applied repetitively in a non-pyramidal tract neurone²⁹. Top traces, current passed through the recording microelectrode; bottom traces, intracellular records. The test e.p.s.ps were evoked by stimulation of the VL nucleus (○); US spikes were elicited from the callosal system (Call, ●). The VL e.p.s.p. had a latency of 1.6 ms and was monosynaptic being able to follow 100 Hz frequency of stimulation. *a*, Neuronal responses during the conditioning and extinction procedures repeated once every second with 27 ms inter-stimulus interval. Following the 110th pairing all the test stimuli elicited spike potentials. The enhanced synaptic response returned to the preconditioning level by about the 21st min of the extinction period. R_m was measured every second with 1.2 nA anodal current pulses. No changes in R_m or spontaneous firing were observed during conditioning. *b*, Time course and specificity of facilitation of test e.p.s.p. for pairing procedure. ● (Paired e.p.s.p.) represents an actual data point every 10th second of the conditioning and every half minute of the extinction period. In the unpaired situation (○), only data at each half-minute intervals are presented.

Fig. 3 Conditioned facilitation of a VL test e.p.s.p. (▼) in a non-pyramidal tract neurone with accompanying membrane depolarization and increases in R_m . The US spikes were elicited by pyramidal tract (PT) stimuli (●). Inter-stimulus interval 30 ms, frequency of pairing 0.5 Hz. Top traces, intracellular records; bottom traces, current records. Only the lower part of action potentials are shown because of high amplification. Calibration: 15 mV for intracellular records and 1.66 nA for current records. Time calibration 15 ms. The amplitude of PT spikes was 71 mV. The test e.p.s.ps and PT spikes were monosynaptically evoked (latency, 1.2 and 4.8 ms at 100 Hz stimulus frequency, respectively). During conditioning the preconditioning value of the amplitude of test e.p.s.ps (mean $\pm$ s.d. 4 ± 0.2 mV, $n = 10$) gradually increased and attained maximal facilitation by the 80th pairing, when each VL stimulus evoked two spikes. Note the conditioned decreases of the mean time to peak of VL e.p.s.ps from 2.7 ± 0.1 to 1.7 ± 0.1 ms ($n = 5$). Parallel with the synaptic facilitation, the R_m increased from 5.1 ± 0.3 to 8.8 ± 0.3 M Ω ($n = 10$), while the membrane potential depolarized from 67 ± 2 to 63 ± 2 mV ($n = 10$). All the conditioned changes of test e.p.s.ps and membrane parameters completely disappeared by the 34th min of the extinction period, when only VL stimuli were given alone with 0.5 Hz frequency. None of the above changes occurred during the pseudo-conditioning procedure, when PT and VL stimuli were randomized.

Intracellular observations in the motor cortex of the cat²⁸ and in invertebrate neurones⁵ have suggested that in some conditions an inward calcium current is initiated which leads, via a second messenger system, to membrane depolarization and an elevation in R_m . On the other hand, the R_m increases associated with conditioned increases in firing rate might be due to a decrease in K^+ conductance⁶. Our observations demonstrate that conditioned increases of synaptic efficacy originate from some kind of, as yet unknown, focal postsynaptic processes in the motor cortex without any general modification of the neuronal excitability. Although concomitant alterations of membrane potential or conductance did occur in some of the conditioned neurones, presumably they represent a different type of plastic modification. The mechanism of synaptic facilitation described here requires further examination.

Response of an insect photoreceptor: a simple log-normal model

Richard Payne & Jonathon Howard

Department of Neurobiology, Research School of Biological Sciences, Australian National University, PO Box 475, Canberra City, ACT 2601, Australia

Photoreceptors respond to light with a graded depolarization or hyperpolarization of the cell membrane. The transduction of light energy to an electrical event, though much studied, remains an outstanding problem in visual research. Previous transduction models¹, involving cascades of chemical reactions, do not fit the responses of insect photoreceptors². It has been proposed that the absorption of light causes the release of an internal transmitter³. We have developed here a simple two-parameter model of transduction based on the assumption that membrane channels are activated when the concentration of internal transmitter reaches a threshold level⁴. The theory predicts that the impulse-response function follows the log-normal curve—this model fits the response of the locust compound eye photoreceptor over the 10-fold range of time scale produced by altering the temperature or the state of light adaptation of the cell.

Photoreceptors in the compound eye of *Locusta migratoria* generate a variable number of superimposed, depolarizing voltage events when stimulated with a brief, weak flash of light⁵. Each event or 'bump' represents an effective quantal absorption of light⁶. The average of a large number of such responses accurately defines the impulse-response function of the receptor. The amplitude of this response increases linearly with increasing flash intensity when the responses have an amplitude of <5 mV and in this linear range, the Fourier transformation of the impulse-response function corresponds to the temporal frequency response of the receptor⁷.

Using glass micropipettes, recordings of electrical potential were made from photoreceptors in an intact eye⁸ and a superfused retina⁹. For the superfused retina we averaged responses from dark-adapted photoreceptors to 1-ms flashes from a green light-emitting diode (Siemens LD57C) at temperatures of the surrounding perfusion fluid between 33 and 17°C. When recording from photoreceptors in an intact eye, a 1-ms test flash from a point light source (also a LED) could be superimposed on steady, adapting illumination from the same source which was

placed on the optical axis of the ommatidium containing the impaled cell.

We attempted to fit our impulse-response functions to the models of Fuortes and Hodgkin¹ and Baylor *et al.*¹⁰. These models are based on the time course of the concentration of the penultimate product of a series of n reactions which proceed sequentially¹ or independently¹⁰. Like Borsellino *et al.*¹¹, we found that the Fuortes and Hodgkin model predicted a response that was too symmetrical about the peak and it also required a range of values of n between 13 and 20 to fit the data from all our cells. The model of Baylor *et al.* fitted the response shape adequately, but required values of n between 20 and 48. The large values for the number of steps required in the reaction chains of these models and the variability from cell to cell made

Fig. 1 *a*, Impulse-response functions recorded from a photoreceptor in an intact eye when dark adapted and at two light-adapted states. One hundred presentations of a 1-ms light flash were averaged in each case. The intensities of the flashes and superimposed adapting light were: 14 photons per facet per flash (dark adapted), 42 photons per facet per flash superimposed on an adapting light of 1.3×10^4 photons per facet per s and 4.2×10^5 photons per facet per flash superimposed on an adapting light of 1.3×10^5 photons per facet per s, wavelength 560 nm. Circles show the fits to the data using equation (1) and the following parameters: DA: $\sigma = 0.31$, $\mu = 74$ ms; LA1: $\sigma = 0.27$, $\mu = 41$ ms; LA2: $\sigma = 0.31$, $\mu = 23$ ms. The amplitudes of the responses were 1.5 (LA1) and 2.3 (LA2) mV. Inset, the impulse-response function in the dark-adapted state is replotted on a logarithmic time scale. Equation (1) (circles) predicts that a gaussian curve will have mean $\mu \exp(-\sigma^2)$ and standard deviation σ . *b*, Impulse response functions of a photoreceptor in a perfused eye at three temperatures. Circles show the fit to the data of equation (1) using the following parameter values: 17°C: $\sigma = 0.305$, $\mu = 22$ ms; 22°C: $\sigma = 0.294$, $\mu = 142$ ms; 33°C: $\sigma = 0.247$, $\mu = 71$ ms. Responses shown are averages of 100 presentations of a flash of intensity 1×10^{12} photons $\text{cm}^{-2} \text{s}^{-1}$ and wavelength 560 nm. Amplitudes of the responses, which have been scaled to 1 mV, were 3.1 (17°C), 3.9 (21°C) and 3.8 (33°C) mV.

us doubt their physical applicability. We therefore searched for an alternative model.

We chose to fit our impulse-response functions to the two-parameter log-normal curve (Fig. 1a)

$$V(t) = sI\Delta t \cdot t^{-1} \cdot \exp[-(\log(t/\mu))^2/2\sigma^2] \quad (1)$$

where I is the intensity of the flash of duration Δt delivered at $t = 0$ and s is the sensitivity of the cell. σ is the standard deviation and μ the mean of the transformed gaussian curve.

An adapting background of intensity 3×10^4 photons per facet per s reduced the value of μ for responses from cells in the intact eye from 60 ± 18 ms ($n = 6$) in the dark-adapted state to 24 ± 2 ms when light adapted. The corresponding values of σ , 0.30 ± 0.01 and 0.32 ± 0.02 , showed no significant change (for example, see Fig. 1a). A large decrease in the sensitivity of the response also occurred during light adaptation as noted by others^{12,13}. Lowering the temperature of the superfused preparation from 33 to 21 °C resulted in an increase in μ from 70 ± 22 ms ($n = 7$) to 160 ± 14 ms. A marginal increase in σ from 0.28 ± 0.02 to 0.32 ± 0.02 also occurred (for example, Fig. 1b). Temperature and light adaptation therefore significantly affect only one temporal parameter in our model (μ), corresponding to a change in the time scale of the response. We propose that this parameter represents the rate constant of a single transduction process, being sensitive to both light adaptation and temperature.

The log-normal distribution has a general application to the analysis of biological data with a large variance¹⁴. In particular, Gaddum¹⁵ and Bliss¹⁶ have used the distribution to describe the variability, from subject to subject, in the critical dose of a drug that will just cause a reaction. We propose an analogous physical model of phototransduction. The model assumes that, following the absorption of light, the strength of a chemical signal increases. The broad impulse-response arises from a scatter in the detection of threshold levels of this signal that trigger the activation of depolarizing ionic channels in the photoreceptive membrane.

Specifically, we assume that: (1) a photoisomerization opens several ionic channels in the vicinity of the activated rhodopsin molecule through the action of an internal transmitter. A given channel opens for a brief time when the concentration of transmitter exceeds a threshold value, α . (2) The threshold

value, α , is normally distributed from channel to channel. (3) The time course of local transmitter concentration following a photoisomerization is a smooth, monotonic function rising from zero at the instant of the stimulus to a positive value, before declining. Its time course is governed by a single time constant, k , so that the transmitter concentration is $y = f(kt)$, where t is the time elapsed after the light flash. (4) The time constant, k , is chosen so as to minimize the temporal width of the voltage generated for a given time to peak of the response t_p .

A direct consequence of assumptions (3) and (4) is that the transmitter concentration, $f(kt)$, increases almost logarithmically with respect to time in the neighbourhood of t_p . This is because, by assumption (4), k is chosen so as to maximize the rate of increase in transmitter concentration, $\partial f(kt)/\partial t$, at $t = t_p$; so that

$$\frac{\partial^2 f(kt)}{\partial k \partial t} = 0 \quad \text{at } t = t_p \quad (2)$$

However, from the identity

$$\frac{\partial f(kt)}{\partial \log t} = t \frac{\partial f(kt)}{\partial t} = k \frac{\partial f(kt)}{\partial k} \quad (3)$$

it follows that for our optimized system

$$\frac{\partial^2 f(kt)}{(\partial \log t)^2} = kt \frac{\partial^2 f(kt)}{\partial k \partial t} = 0 \quad \text{at } t = t_p \quad (4)$$

Integrating equation (4) twice with respect to $\log(t)$ yields $f(kt) = a \log(t) + b$ in the neighbourhood of t_p (a, b constant). The impulse-response function represents the sum of the voltages generated by all the channels that open following a light flash. This population of channels has, by assumption (2), thresholds to transmitter concentration that are normally distributed. If the concentration of transmitter rises logarithmically with time it follows that the temporal frequency of opening of channels will be log-normal so that, if channel opening times are brief, the voltage generated will follow equation (1). The model is illustrated in Fig. 2.

Our model describes the photoreceptor response as the result of a variable threshold associated with a process that is logarithmically related to time. Of the two temporal parameters only μ , which describes the rate of release of the internal transmitter, is significantly affected by temperature or light adaptation. We intend to continue our investigations by examining the response of 'faster' insect eyes, such as those of the fly and dragonfly. If equation (1) can be applied to other photoreceptors, then the two parameters, μ and σ , will provide a simple method of comparing their temporal frequency response, similar to the parameters describing the approximately gaussian angular sensitivity curves of photoreceptors¹⁷.

Fig. 2 Illustration of the physical model proposed in the text. The Gaussian curve describing the thresholds for the opening of channels is transformed into the asymmetric impulse-response through the non-linearity of the rising 'transmitter' concentration. The Langmuir isotherm, $y = kt/(1 + kt)$ is chosen to describe the transmitter concentration, y . In the region of the activation of channels, between $y = 0.3$ and 0.7 , this equation is approximated by $y = 0.25 \log(t) + c$. Choosing to activate channels in this logarithmic region provides for the least scatter in channel opening times.

Choline biosynthesis by a preparation enriched in synaptosomes from rat brain

Jan K. Blusztajn & Richard J. Wurtman

Laboratory of Neuroendocrine Regulation, Department of Nutrition and Food Science, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA

It is widely held that brain cells are unable to synthesize choline *de novo*, and that the only source of this compound for brain acetylcholine or membrane biosynthesis is the choline or choline-containing phospholipids taken up from the circulation¹. This notion has been difficult to reconcile with observations²⁻⁴ that there is a net efflux of choline from the brain. Recently we⁵ and others^{6,7} have demonstrated that various preparations of mammalian brain contain enzymes, the phosphatidylethanolamine *N*-methyltransferases (PeMT), which catalyse the synthesis of phosphatidylcholine (PC), using *S*-adenosylmethionine (SAM) as a methyl donor for the stepwise methylation of phosphatidylethanolamine (PE). The highest specific activity of PeMT was present in synaptosomal preparation^{5,6}. We now report that rat brain synaptosomal preparations can also metabolize the PC generated by PeMT to liberate free choline.

Male Sprague-Dawley rats (180–220 g, Charles River) were housed under light (Vita-Lite, Duro-Test) for 12 h daily and had free access to water and food (Charles River Rat Chow). Animals were decapitated, their brains quickly dissected and synaptosomal preparations of whole brains (excluding cerebellum) were obtained as described previously⁵; their identity was confirmed by electron microscopy. Synaptosomal preparations were incubated in Krebs-Ringer bicarbonate buffer (pH 7.4) at 37 °C. Heat-treated synaptosomes (100 °C, 20 s) were used to generate blank values. Phosphatidyl-*N,N*-dimethylethanolamine (P2) (Gibco) was used as PeMT substrate, and [*Me*-³H]*S*-adenosylmethionine (10 mCi μ mol⁻¹, NEN) as the methyl donor. Enzymatic reactions were stopped by addition of the appropriate extraction solution. Phospholipids were extracted and purified as described before⁵, and the ³H-methyl present in newly formed ³H-PC was quantified by liquid scintillation spectrophotometry. The choline, including [*Me*-³H]choline, was extracted from the incubation media with 0.5% tetraphenylboron (Aldrich) in heptanone (Aldrich), and back-extracted from the heptanone phase into 0.4 M hydrochloric acid. The aqueous layer was then dried under vacuum, and the dry residue redissolved in ethanol and subjected to

Fig. 1 Purification of newly synthesized choline. Synaptosomal preparations (0.5 mg protein) were incubated at 37 °C for 30 min in 0.1 ml Krebs-Ringer bicarbonate buffer (pH 7.4) containing: 4.5 μ M [*Me*-³H]SAM (10 mCi μ mol⁻¹), 50 μ g of ultrasound-dispersed P2, and 1,700 d.p.m. of [*Me*-¹⁴C]choline (60 mCi mmol⁻¹). The reaction was stopped by addition of 0.3 ml of 0.5% tetraphenylboron in heptanone. The choline in the heptanone was back-extracted to 0.3 ml of 0.4 M HCl, which was then dried under vacuum. The dry residue was then redissolved in 0.05 ml of ethanol and applied to cellulose TLC plates (a) or to filter paper for electrophoresis (c). The TLC solvent system contained: *n*-butanol/ethanol/acetic acid/water 40:10:1:15 (by volume). The electrophoretic conditions were: 0.75 M acetic acid, 0.75 M formic acid pH 2.0, constant voltage of 17 V cm⁻¹ for 40 min. Each sample also contained 5 μ g of choline chloride carrier. The plates and papers were stained for choline¹⁶, and segments staining positively were extracted with 50% ethanol in 0.2 M HCl. The extracts were then concentrated and rechromatographed as described above, except that TLC-derived material (a) was subjected to electrophoresis (b), while electrophoresis-derived material (c) was subjected to TLC (d). a, b, c and d show distributions of radioactivity on chromatograms prepared as described above. Shaded areas indicate segments which stained positively for choline. Lower panels show the distribution of ¹⁴C-choline standards and provide estimates of choline recovery. Incubations using heat-treated synaptosomal preparations yield flat background radioactivity patterns in b and d.

Table 1 Phosphorylation of newly synthesized choline by choline kinase

	Choline (d.p.m.)	Phosphorylcholine (d.p.m.)
Control	257 $\pm$ 22	0 (background)
Choline kinase	31 $\pm$ 7	323 $\pm$ 51

Incubations, extractions and TLC prepurification of newly synthesized choline were carried out as in Fig. 1 legend. Choline was extracted from TLC plates with 50% ethanol in 0.2 M HCl and the extracts were then dried under vacuum. The dry residues were resuspended in 0.1 ml of medium containing 12 mM glycylglycine, 8 mM dithiothreitol, 18 mM MgCl₂, 1.2 mM ATP and 0.05 U choline kinase (pH 7.4), and incubated for 15 min at 30 °C. Reaction was stopped with 0.1 ml ethanol and the mixtures concentrated and subjected to paper electrophoresis (as described in Fig. 1 legend). Segments were visualized for choline¹⁶ and phosphorylcholine¹⁷ and then the radioactivity counted. Data are expressed as means $\pm$ s.d.

paper electrophoresis⁸ and TLC. As described below, procedures were needed to reduce background radioactivity. The radioactivity in segments of the chromatograms was determined by liquid scintillation spectrophotometry. The recovery of choline was calculated by adding ¹⁴C-choline internal standard to synaptosomal incubations. The ³H-choline formed enzymatically was established by subjecting the water-soluble products of the methylation prepurified by TLC, to phosphorylation by choline kinase, purifying the products by paper electrophoresis. To determine the ratio of choline and PC in the incubations, a radioenzymatic assay of choline⁹, using choline [γ -³²P]ATP; the PC was purified by TLC and acidified before assay.

Identification of newly synthesized choline proved relatively difficult. It was not until we combined TLC and paper electrophoresis that we could see a sharp ^3H -methyl radioactive peak that co-migrated with authentic nonradioactive and ^{14}C -choline (Fig. 1). The heat-treated preparation of synaptosomes produced no radioactive product that would co-migrate with authentic choline in either of these chromatographic systems. After subjecting the ^3H -methyl material that had co-chromatographed with authentic choline to phosphorylation by choline kinase, virtually none of the radioactivity co-chromatographed with choline (Table 1). The radioactivity could, however, be recovered from material co-migrating with phosphorylcholine, as would be expected if the ^3H -methyl material were authentic choline.

The rate of incorporation of ^3H -methyl groups into choline depended on the concentration of PeMT substrate present—addition of increasing amounts of P2 to incubation mixtures (Fig. 2) caused parallel increases in the apparent rates of synthesis of PC and choline until saturation occurred at $\sim 500\ \mu\text{g}$ P2 per ml. This increase in apparent synthesis rate was more pronounced for ^3H -PC, where the ratio of rate of ^3H -methyl incorporation when 1 mg per ml of P2 was present to incorporation without added P2 was 5.7; the same ratio for ^3H -choline was only 1.5. Addition of dimethylethanolamine (30 mM final concentration) did not enhance the synaptosomal formation of choline (data not shown). These results indicate that the ^3H -choline must have been formed by degradation of newly synthesized PC, or, less likely, by action of some as yet undiscovered enzyme on a degradation product of P2.

The SAM concentration at which our assay was carried out ($4.5\ \mu\text{M}$) is below the apparent K_m for PeMT^{5,6}. However, at this SAM concentration the reaction proceeded linearly with time for up to 50 min. The incorporation of ^3H -methyl into ^3H -PC proceeded at the rate of 1.3 pmol per mg protein per 30 min, and into ^3H -choline at 0.4 pmol per mg protein per 30 min (Table 2). The choline newly formed during this interval would represent 88 p.p.m. of the total choline in the synaptosomal preparation, whereas the newly formed PC would represent only 1.9 p.p.m. of total PC (Table 2). Thus the relative enrichment of the choline pool was 47-fold greater than that of PC. These results suggest that there may exist specific physical domains of phospholipids within synaptosomal membranes, such that the PE methylation and PC degradation occur in the same domain. This would explain why up to 23% of the [^3H]choline present in the incubations could be recovered as free choline molecules and not covalently bound in the form of PC, while free choline constituted <1% of the total amount of

Table 2 Comparison of synthesis of phosphatidylcholine and choline by rat brain synaptosomal preparations

	Phosphatidylcholine	Choline
^3H -methyl incorporation (pmol per mg protein per 30 min)	1.323 ± 0.219	0.396 ± 0.086
Concentration (nmol per mg protein)	708 ± 29	4.5 ± 0.82
Specific activity (p.p.m.)	1.87 ± 0.37	88 ± 34
I_{Ch}	0.30	
I_{PC}		
SA_{Ch}	47.3	
SA_{PC}		

Incubation, extraction and purification conditions were as described in Fig. 1 and Table 1 legends. Free ^3H -choline and ^3H -choline hydrolysed off ^3H -PC were determined by radioenzymatic assay⁹. Data are expressed as means $\pm$ s.d. ^3H -methyl incorporations are I_{PC} and I_{Ch} , specific activities are SA_{PC} and SA_{Ch} for phosphatidylcholine and choline, respectively.

choline (that is free plus PC-bound) in the synaptosomal preparations (Table 2). Other studies have suggested the existence of two PC pools in synaptosomes, one with a $t_{1/2}$ of 2 days and another with $t_{1/2}$ of 52.5 days (ref. 10). Our results indicate the existence of yet another pool, which turns over much more rapidly, and which contains PC molecules derived from the PeMT pathway.

The brain is reported to contain several enzyme systems able to catalyse the degradation of PC to liberate free choline: phospholipases A_1 and A_2 and lysophospholipase¹¹ generate glycerol-3-phosphorylcholine, which can subsequently be hydrolysed in a one-step¹² or two-step process¹³ to yield free choline; phospholipase D can catalyse PC hydrolysis to liberate free choline directly¹⁴; lysophospholipase D could liberate choline from lysophosphatidylcholine formed by the action of phospholipase A_2 (ref. 15). Our data do not indicate which, if any, of these enzyme systems liberate ^3H -choline from ^3H -PC formed in synaptosomal preparation by the transmethylation pathway—our present techniques are insufficient to detect other [^3H]choline containing species, which might provide clues.

It seems clear that previously, by measuring only phospholipid products, we⁵ and others^{6,7} have underestimated the contribution of PeMT to brain choline. It is entirely possible that other compounds, such as glycerol-3-phosphorylcholine and phosphorylcholine, also accumulate in our experimental system as intermediates in the genesis of free choline; thus we may still be underestimating the total rate of choline production in the brain. The absolute contribution of *de novo* synthesis to total brain choline and the extent to which this source provides precursor molecules for acetylcholine formation await further study.

These studies were supported in part by a grant from the National Institute of Mental Health. We thank Mr Robert Scheinman for technical assistance.

ATP-stimulated endoprotease is associated with the cell membrane of *E. coli*

Richard W. Voellmy* & Alfred L. Goldberg

Department of Physiology, Harvard Medical School, Boston, Massachusetts 02115, USA

Despite knowledge of the physiological significance and regulation of protein degradation in bacteria¹⁻⁷, the pathway of proteolysis and the responsible enzymes are still not known. Degradation of cell proteins in bacterial and animal cells requires continuous ATP production^{1,8}, inhibition of which in *Escherichia coli* prevents the degradation of normal proteins in growing cells⁸, accelerated breakdown of such proteins in starving cultures^{3,9} and the very rapid breakdown of abnormal proteins^{8,10}. Intracellular proteolysis proceeds by repeated endoproteolytic steps and ATP is required for the initial cleavages of the substrate¹⁰. We have recently demonstrated ATP stimulation of proteolysis in extracts of bacterial and animal cells¹¹⁻¹⁵. These ATP-stimulated systems seem to be responsible for the rapid degradation of abnormal proteins¹¹⁻¹⁴ *in vivo*, but they may also be involved in the catabolism of normal cell proteins^{1-3,9}, limited proteolysis, such as the processing of precursors for secreted or membrane proteins¹⁶⁻²⁰, and the selective inactivation of specific proteins, as occurs in the ATP-dependent cleavage of the lambda repressor by the recA protein²¹. We report here that membrane fragments contain an ATP-stimulated protease that degrades cell proteins to large peptides (of molecular weight (MW) 71,500) which are then rapidly hydrolysed to amino acids by soluble ATP-independent enzymes.

When extracts of freshly grown *E. coli* were prepared by gentle methods (by grinding with alumina, by using the French press at 3,000 p.s.i., or by freezing and thawing followed by lysozyme treatment and osmotic shock¹³), the degradation of [*Me*-¹⁴C]globin^{13,22} was stimulated two- to fourfold by addition of ATP (3 mM). With less gentle methods of lysis (the French press at 12,000–15,000 p.s.i., repeated freezing and thawing followed by lysozyme treatment, or sonication), the resulting extracts contained high levels of proteolytic activity but showed very little (<25%) stimulation by ATP¹³.

Approximately 70–80% of the proteolytic activity after gentle cell lysis was recovered on the pellet resulting from centrifugation at 160,000g for 60 min (Table 1). When these pellets were resuspended, they showed ATP-stimulated proteolysis. The proteolytic activity remaining in the supernatant was not affected by ATP (Table 1).

When these extracts were analysed by gel filtration on Sepharose 2B or 4B, most of the ATP-stimulated activity was eluted in the void volume ahead of 70S ribosomes (Fig. 1), and is thus associated with large particulate material. Some soluble proteolytic activity eluted with the bulk of cell protein of molecular weights less than that of β -galactosidase (MW 540,000). This latter activity (see below and refs 29, 39, 40) showed a much smaller stimulation by ATP than did the peak in the void volume, in which ATP increased proteolysis two- to fivefold. Identical elution patterns were obtained when gel filtration was repeated on the material in the void volume or was performed in the presence of 3 mM ATP. Therefore, ATP does not stimulate proteolysis by releasing the proteolytic activity from a bound to a free state.

This high-molecular-weight fraction contains polyribosomes and membrane fragments, as indicated by a high content of the (Ca²⁺ + Mg²⁺)ATPase (Fig. 2) and many membrane vesicles

Fig. 1 Fractionation of *E. coli* proteolytic activity on Sepharose 4B. An extract from *E. coli*, prepared by grinding with alumina (50 mg protein), was filtered through an 80 × 2.5 cm column of Sepharose 4B equilibrated with 10 mM Tris-HCl, 10 mM MgCl₂, 50 mM KCl and 0.5 mM dithiothreitol (pH 7.5). Proteolytic activity was determined with (●) and without (×) an ATP-generating system as in Table 1 legend. β -galactosidase was assayed using *o*-nitrophenyl- β -D-galactoside as a substrate¹⁰. Similar data were obtained with extracts prepared as in Table 1 legend.

were evident in the electron microscope (in collaboration with Dr Richard Goldstein). When the extracts were incubated with puromycin (50 μ g ml⁻¹) for 5–10 min at 37 °C or with ribonuclease A (100 μ g ml⁻¹) before gel filtration to convert polysomes to monosomes²³, or when cells were incubated for 15 min at 10–15 °C before their collection to release ribosomes from the RNA²³, the ATP-stimulated proteolytic activity still eluted in the void volume of Sepharose 4B. Thus it could not have been associated with the polysomes.

Extracts subjected to sucrose density centrifugation showed maximal proteolytic activity at 47.5% sucrose (Fig. 2), the same density as membrane fragments prepared from marker cells grown in parallel in the presence of ³H-oleate to label membrane lipids. The maximal activity of the membrane-associated (Ca²⁺ + Mg²⁺)ATPase was also found in these same lipid-containing fractions (Fig. 2).

If the ATP-stimulated protease is membrane-associated, it should co-precipitate on incubation with an antibody directed against another membrane protein. As membrane vesicles prepared by grinding or French press are inverted²⁴, an antibody against an inner membrane protein, the F₁ ATPase, was used. When it was incubated with the fraction purified by gel filtration (Fig. 1), it is precipitated most (76–90%) of the membrane-bound ATPase (data not shown) and reduced the proteolytic activity in the supernatant (Table 2). By contrast, when the antibody was added to the soluble proteolytic activity obtained by gel filtration (Fig. 1), no inhibition of globin hydrolysis was observed. A control immunoprecipitation was also carried out with purified exogenous elongation factor G (EFG) and an antibody directed against this protein (Table 2). The concentrations of EFG and anti-EFG were adjusted such that a similar amount of protein precipitated in these conditions to that which precipitated with the antibody against the membrane ATPase. Virtually none of the membrane-associated proteolytic activity was lost from the supernatant.

Previous studies^{1,25,26} have demonstrated appreciable proteolytic activity in membrane fractions prepared by low speed centrifugation. We therefore tested whether this fraction contained the ATP-stimulated proteolytic system. Cells lysed by freezing and thawing followed by lysozyme treatment and osmotic shock, and the extracts were centrifuged for 10–15 min to remove unbroken cells and then at 25,000g for 20 min. The pellets of the second spin were very rich in hydrolysing ¹⁴C-globin, but this reaction was not stimulated by ATP (3 mM). However, in the presence of 10 mM sodium cyanide (an ATPase inhibitor), ATP caused a clear stimulation of globin degradation (data not shown), suggesting that a (Ca²⁺ + Mg²⁺)ATPase is not essential for the stimulation of proteolytic activity, in accord with findings on

* Present address: Department of Molecular Biology, University of Geneva, Geneva, Switzerland.

Table 1 Distribution of the ATP-stimulated proteolytic activity on ultracentrifugation

Fractions	Proteolytic activity (c.p.m.)		% Stimulation by ATP
	Without ATP	With ATP	
Crude extract	5,490	14,260	160
Pellet after second wash	3,831	8,772	129
Supernatant of first wash	1,850	1,860	—
Supernatant of second wash	804	792	—

E. coli K12 strain NF172 (ref. 9, 500-ml portions) was grown in Luria broth⁴² at 37 °C with vigorous aeration. The cells were cooled rapidly and collected at an A_{550} of 1.0. Three litres of cells were lysed by grinding with alumina for a short period. The resulting crude extract in buffer I (25 mM Tris-HCl pH 7.5, 20 mM MgCl₂, 0.5 mM dithiothreitol) was then centrifuged at 12,000g for 20 min. The supernatant was dialysed overnight against buffer I, and an aliquot of this crude extract was assayed for proteolytic activity. The dialysed extract was spun at 120,000g for 75 min. The pellets were resuspended in this buffer and centrifuged again. The pellet from this first wash was resuspended once more and centrifuged as before. The final pellets were resuspended in the original volume of buffer I, and together with the supernatants of the washes were assayed for proteolytic activity in the presence or absence of ATP and an ATP-generating system. The hydrolysis of [*Me*-¹⁴C]- (apo)haemoglobin^{13,22} to acid-soluble material was used to estimate proteolytic activity. Incubation mixtures contained 1 ml of extract, 10 μ l of ¹⁴C-globin (~15,000 c.p.m.) and 50 μ l of an ATP solution (60 mM) or an ATP-generating system (60 mM ATP, 250 mM phosphocreatine, 0.4 mg ml⁻¹ creatine phosphokinase, rabbit muscle type I [Sigma]). Incubations were carried out at 30 °C for 60–90 min. Comparisons between the absolute proteolytic activity in the crude extracts, supernatants and pellets may be misleading as these fractions contained very different amounts of nonradioactive proteins that may compete with the ¹⁴C-labelled substrate. Qualitatively, similar data were obtained when the pellets were resuspended in buffer I containing 0.5 M KCl or 1 mM Tris-HCl (pH 7.5), although these conditions reduced the degree of stimulation by ATP.

Furthermore, in related experiments (data not shown) we have demonstrated ATP-stimulated proteolysis in membrane vesicles of mutants²⁷ that lack a functioning (Ca²⁺ + Mg²⁺) ATPase (AN120, an *uncA*⁻ strain).

The acid-soluble products of protein breakdown were analysed by gel filtration on Sephadex G-15. Crude *E. coli* extracts, prepared by alumina grinding, and the membrane fraction, isolated by gel filtration on Sepharose 4B, were incubated in parallel with either ¹⁴C-globin or ³⁵S-labelled *E. coli* protein (denatured with acid to inactivate proteases). Both substrates were hydrolysed on these extracts to acid-soluble material by an ATP-stimulated process (stimulation was 100–200% with globin and 70–100% with the *E. coli* proteins). The crude extracts degraded the ³⁵S-proteins to amino acids (Fig. 3) and thus can carry out the complete degradation of cell proteins, in similar fashion to intact cells. The [*Me*-¹⁴C]globin was hydrolysed to dipeptides. Related observations suggest that the labelled methyl group on the lysine prevents the hydrolysis of dipeptides by certain amino-peptidases.

When either substrate was incubated with the purified membrane fraction, most of the resulting acid-soluble ³⁵S- or ¹⁴C-products eluted close to the void volume. Very little was in the form of amino acids or even dipeptides (Fig. 3). The sizes of these proteolytic products did not differ whether or not ATP was present (data not shown). The ATP-stimulated proteolytic activity generated mainly peptides of MW 1,500 or greater²⁸ which were not degraded further. Thus the rate-limiting step in protein degradation in these extracts is an ATP-stimulated endoproteolytic cleavage, in accord with *in vivo* findings¹⁰. This initial step is membrane associated, while soluble cytoplasmic enzymes (exo- and endopeptidases^{6,29,30}) catalyse the subsequent conversion of the peptides to free amino acids. Thus, the ³⁵S-labelled peptides generated by the membrane fraction were mixed with the soluble fraction obtained by

Fig. 2 Sucrose-density centrifugation of the particulate proteolytic activity. An extract prepared with the French press at 3,000 p.s.i. was centrifuged at 12,000g for 20 min. The supernatant was spun for 60 min at 12,000g and the resulting pellet washed once and resuspended in buffer I. For measurements of proteolytic activity against ¹⁴C-globin (see Table 1) and ATPase activity, 5–10 mg of the pelleted material were applied to linear sucrose gradients (32.5 ml) ranging from 25–65% and spun for 24 h at 25,000 r.p.m. in a SW27 rotor. Fractions (65 drops) dialysed against buffer I to remove the sucrose were assayed for proteolytic activity. To identify the fractions containing membrane lipids, cells were grown in medium containing ³H-oleate (28.5 mCi per mg, NEN). Extracts from the ³H-oleate-labelled cells were spun in parallel, and the radioactivity in each fraction measured (lower panel). To assay ATPase activity, 0.5-ml portions of the fractions were incubated with 0.5 mM ATP for 45 min at 30 °C. The samples were then boiled, and their ATP content measured using the firefly luciferase assay^{8,9}.

centrifugation (Table 1) of the crude extract, they were quickly hydrolysed to free amino acids. This latter reaction was not stimulated by ATP.

Although a large fraction, perhaps most, of the ATP-stimulated proteolytic activity is associated with the cell membrane, we cannot conclude what per cent of the proteolytic activity is actually membrane bound *in vivo* or even in these cell-free extracts, because the soluble and membrane fractions contain very different amounts of peptidases (Fig. 3) and of nonradioactive proteins that serve as competing substrates. A localization of the ATP-stimulated proteolysis on the inner cell membrane seems likely as alumina grinding and the French Press at low pressures create primarily inverted membrane vesicles, which should be impermeable to ATP and ¹⁴C-globin. Furthermore, protein breakdown in intact cells is completely dependent on the continuous production of ATP^{1,3,8–10} and therefore requires contact with the intracellular nucleotide pools. However, these studies have not eliminated conclusively a possible association with the outer cell membrane³¹. As the existence of proteases free within a cell might be harmful, an association with the membrane could reduce the frequency at which critical enzymes are inappropriately hydrolysed. This localization may also affect the selectivity of protein breakdown. Bacteria, like animal cells, degrade soluble proteins with highly abnormal conformations especially rapidly^{1,2,4–7,10–12}. Such partially unfolded proteins probably have more hydrophobic regions exposed on their surface than do normal ones^{1,12} and, therefore, may bind differentially to the cell membrane. It is perhaps relevant that when bacteria make large amounts of abnormal proteins, these molecules associate in intracellular aggregates that lie adjacent to the surface membrane^{32,33}.

On the cell membrane, the ATP-stimulated endoprotease may also be important in the turnover of membrane components

Fig. 3 Size distribution of the acid-soluble material produced by the membrane-associated protease and the crude extract. Cells were lysed by grinding with alumina. One portion of the extract was filtered through Sepharose 4B, and the fractions containing the membrane-associated protease were pooled and concentrated by ultrafiltration. This material (○) and a portion of the crude extract (●) containing an equal amount of protein were incubated with ^{35}S -labelled denatured *E. coli* protein for 2 h at 30 °C in the presence of an ATP-generating system. The protein was then precipitated with 10% trichloroacetic acid, and the supernatants applied to a 2 × 78 cm column of Sephadex G-15 in 0.05 M Tris-HCl (pH 7.5). Trileucine and leucine were run as molecular weight markers and were assayed with fluorescamine²⁶. To prepare ^{35}S -labelled *E. coli* proteins, 10 ml of strain NF 161 (*spoT⁻, arg⁻, met⁻*) were grown on glucose minimal medium⁸ containing arginine (60 $\mu\text{g ml}^{-1}$), a limiting amount of methionine (1.5 $\mu\text{g ml}^{-1}$) and 0.5 mCi of ^{35}S -methionine (460 Ci nmol⁻¹, NEN). When growth ceased, the cells were centrifuged and washed with 10 ml of growth medium lacking ^{35}S -methionine. The cells were then treated with 10% trichloroacetic acid. After centrifugation, the pellet was dissolved in 1 M NaOH and the pH adjusted to 7.0 with HCl. Before use, the suspension was dialysed extensively against buffer I.

and in the processing of secreted periplasmic or membrane proteins from larger precursors^{16-19,21} a process believed to occur on the inner cell membrane^{17,21,37}. Inner membrane vesicles are able to process membrane protein^{17,20}, and this reaction seems to depend on the high-energy membrane state^{34,35}. Further characterization of the 'signal peptidase(s)' and the membrane-associated globin-degrading activities should clarify whether these proteolytic systems are in some way related. In addition, the ATP-stimulated enzyme may be involved in the rapid degradation of the released signal peptides.

These findings raise the possibility that the effect of ATP is mediated by some membrane-related function. However, there is strong evidence that the high-energy membrane state is not required for protein breakdown *in vivo*⁸, and uncoupling agents do not inhibit the ATP effect in these membrane preparations (data not shown). The present studies have also ruled out an involvement of the $(\text{Ca}^{2+} + \text{Mg}^{2+})\text{ATPase}$. Moreover, when *E. coli* are lysed by less gentle methods than were used here, we can isolate from the soluble fraction an ATP-dependent endoprotease, as well as seven ATP-independent proteases^{29,38-40}. Therefore, a membrane-association is not essential for the effect of ATP on protein degradation. After purification^{29,41}, the soluble ATP-dependent enzyme resembles strongly the membrane-associated activity described here²⁹. Possibly the soluble enzyme is derived from the membrane fraction, or alternatively the bacteria may contain two distinct ATP-stimulated proteolytic systems that serve different physiological functions.

Table 2 Loss of proteolytic activity on treatment with antibody against membrane-associated ATPase

Source of proteolytic activity	Additions	Activity remaining in supernatant (c.p.m.)	% Proteolytic activity lost from supernatant
Particulate fraction	Rabbit IgG	4,661	0
	anti-ATPase (EFG) + anti-EFG	2,876	39
Soluble fraction	Rabbit IgG	4,455	4
	Anti-ATPase	5,677	0
		5,239	8

An extract prepared by grinding with alumina was chromatographed through Sepharose 4B. The peaks of proteolytic activity in the void volume (particulate activity) and in the soluble fraction were separated by gel chromatography as in Fig. 1. Portions (1 ml) of the two fractions in buffer I were incubated with antibody for 24 h at 4 °C. Precipitates were removed in a refrigerated clinical centrifuge, and proteolytic activity against ^{14}C -globin in the supernatants was assayed in the presence of an ATP-generating system (Table 1). The purified IgG fractions ($A_{280} = 0.57$) or purified EFG ($A_{280} = 0.02$) were added to 1 ml of the protease preparations. All antisera were purified by ammonium sulphate fractionation and chromatography on diethylaminoethyl and CM-cellulose⁴³ to remove the associated proteolytic activity. The purified IgG fractions contained no measurable activity against ^{14}C -globin.

We thank Dr P. C. Tai for advice and for providing pure ribosomes and ribosomal subunits, Dr F. Gibson for strain AN120, Professor L. Heppel for the antibody against membrane ATPase, and Ms Robin Levine for assisting in the preparation of this manuscript. During this work, R. W. V. was a Fellow of the Swiss National Fund. These studies were supported by grants from the National Institute of Neurobiological Diseases and Stroke and the Juvenile Diabetes Fund.

Two mutations that alter the regulatory activity of *E. coli* *recA* protein

Jeffrey W. Roberts & Christine W. Roberts

Section of Biochemistry, Molecular and Cell Biology,
Wing Hall, Cornell University, Ithaca, New York 14853, USA

The *Escherichia coli* *recA* gene product is both a direct participant and a central regulatory element in important processes of DNA repair, including one that is probably responsible for all radiation mutagenesis and some chemical mutagenesis. It has the direct function of catalysing pairing of single-stranded DNA to a homologous region in duplex DNA^{1,2}, a reaction thought to be fundamental to genetic recombination. This activity of *recA* protein probably contributes to DNA repair by promoting recombination between damaged DNA molecules³. We have shown that *recA* protein also has a regulatory function, mediated by its ability to destroy repressors and possibly other proteins by proteolytic cleavage, leading to the induction of certain genes⁴⁻⁶; these include *recA* itself, regulated by the *lexA* gene product⁷⁻⁹, other genes probably involved in DNA repair, some of which are also regulated by the *lexA* gene product¹⁰, and the early genes of temperate bacteriophages, which are regulated by their repressors. *recA* protein is activated to cleave repressors *in vitro* by interaction with ATP (or the ATP analogue ATP- γ S) and a polynucleotide such as single-stranded DNA⁴, probably the same interaction that initiates the strand-pairing reaction¹¹. We have proposed that *recA* protein is also activated to attack repressors *in vivo* when it interacts with single-stranded DNA; DNA-damaging treatments such as UV-ray irradiation would thereby invoke the *recA*-dependent functions of recombination, repair, mutagenesis and prophage induction⁴. As further evidence that the proteolytic activity of *recA* protein is responsible for its regulatory function, we show here that the ability of two mutationally altered *recA* proteins to cleave phage λ repressor correlates with the ability of the mutant cells to induce prophage.

Both mutations *recA142* and *recA430* (formerly named *lexB30*) prevent phage repressor inactivation after inducing treatments, but they affect *recA* function in the cell differently. (1) The mutant *recA142* is defective in genetic recombination, like classical *RecA*⁻ mutants, and it does not induce λ prophage after normal inducing treatments¹². Unlike most *RecA*⁻ mutations, however, *recA142* supports spontaneous induction, an unprovoked but *recA*-dependent basal level of induction that occurs in wild-type lysogens (ref. 12 and Table 1). A λ repressor fragment characteristic of *recA*-mediated cleavage results from this spontaneous induction in both wild-type and *recA142* lysogens¹³. We thus expected that *recA142* protein would be able to cleave λ repressor in some conditions *in vitro*, but might have some defect in the interaction with DNA thought to initiate both strand pairing and repressor cleavage. (2) The mutant *recA430* was selected by Devoret and Blanco^{14,15} to be defective in λ induction, and it neither responds to inducing agents nor displays spontaneous induction (ref. 14 and Table 1). Furthermore, *recA* protein is not amplified in a *recA430* mutant cell in response to inducing treatments^{16,17}. Although the *recA430* mutation maps in the *recA* gene^{17,18}, conjugation crosses in the *recA430* cell produce nearly normal numbers of recombinant progeny. We expected that *recA430* protein would be unable to cleave λ repressor, but might be normal in activities required for genetic recombination.

To provide a source of these mutant proteins, we used strains carrying the *lexA* gene mutation *spr-51* (ref. 7), which is thought to inactivate a repressor of the *recA* gene and thus cause overproduction of *recA* protein^{5,19}. We confirmed that these derivatives maintain the *recA* phenotypes of the original

Fig. 1 Repressor cleavage directed by purified mutationally altered *recA* proteins. Reaction mixtures of 30 μ l were constructed as described previously⁴, except that they contained 2 mM MgCl₂, 1 mM ATP- γ S, 0.047 M NaCl, 0.013 M NaCl, 1.5 μ g *recA* protein, 3 μ g λ repressor and 0.039 μ g denatured λ DNA. After incubation for 3 h 20 min at 37°C, the reaction mixtures were subjected to SDS-gel electrophoresis and the gel was stained as described previously⁴. The *recA* protein concentration was calculated from a measured absorbance at 280 nm of 0.60 units mg⁻¹ ml⁻¹, corrected from the previously assumed 1.0 units mg⁻¹ ml⁻¹ (ref. 4). Track a, *recA*⁺ protein; track b, *recA441* protein (formerly named *tif-1*); track c, *recA430* protein; track d, *recA142* protein. R, λ repressor; R₁ and R₂, proteolytic fragments of λ repressor. *recA* protein and λ repressor were prepared as described elsewhere⁴. *recA430* protein was prepared from the *spr-51 recA430* strain KM1193, obtained from K. McEntee. *recA142* protein was prepared from the *spr-51 recA142* strain JR235, constructed by P1 transduction of DM1420 (ref. 7) to *srl300*:Tn10, followed by transduction to *Sr1*⁺ by P1 grown on the *recA142* strain JC4728 and screening for sensitivity to UV-light irradiation.

mutants, in that a λ lysogen of *spr-51 recA142* displays spontaneous induction whereas a lysogen of *spr-51 recA430* does not (data not shown). Like its *spr*⁺*recA142* parent, the *spr-51 recA142* strain shows by patch tests the high sensitivity to killing by UV-ray irradiation characteristic of *recA*⁻ mutants (data not shown). The parental *spr*⁺*recA430* mutant is moderately UV sensitive¹⁵; its *spr-51* derivative is less sensitive by patch tests, but still distinctly more sensitive than wild type.

We tested the ability of *recA* protein purified from *recA142* and *recA430* bacteria to cleave λ repressor in the single-stranded DNA and ATP- γ S dependent reaction. Figure 1 shows that *recA142* protein is active, whereas *recA430* protein is not. In control reactions, both wild-type *recA*⁺ protein and protein from the *recA* mutant *tif-1* (refs 5, 20) (renamed *recA441*), which displays constitutive expression of *recA*-dependent functions, are active. From densitometric scanning of stained repressor fragments produced during a time course, we determined that the *recA142* protein cleaves λ repressor at ~75%

the rate of wild type in the presence of ATP- γ S (11 compared with 15 ng repressor cleaved per min per μ g recA protein). In contrast, Fig. 1 implies that recA430 protein could cleave λ repressor at no more than 2% the rate of wild type. We tested the mutants in conditions that provide the highest cleavage rate with wild-type recA protein⁴, but observed no repressor cleavage by recA430 protein in other conditions—ATP instead of ATP- γ S, higher concentrations of DNA, or oligonucleotides substituted for λ DNA.

recA protein is a single-stranded DNA-dependent ATPase^{4,21-23} whose activity is probably essential to strand exchange, as this requires ATP hydrolysis^{2,11}. Figure 2 shows that recA430 protein has normal ATPase activity, consistent with its normal function in recombination. This result also shows that the protein we prepared was not destroyed during cell lysis and purification. The recA430 protein also is equivalent to the wild type in DNA-dependent entrapment of radioactive ATP- γ S on a membrane filter (data not shown), and is active in reannealing homologous single strands of DNA, possibly a partial reaction of the strand-pairing activity⁹. Thus, we conclude that recA430 protein is specifically defective in cleaving phage λ repressor, and that this defect accounts for the failure of λ to be induced in recA430 bacteria.

The recA142 protein, which does not effectively support recombination *in vivo*, is also an active ATPase *in vitro* (Fig. 2). However, its activity is much more sensitive to ionic strength than that of wild-type recA protein, displaying only 10% of the activity of the wild type at 0.20 M NaCl. This suggests a weaker interaction of the recA142 protein with DNA in the presence of ATP that could account both for the recombination deficiency of the mutant and for its failure to cleave λ repressor in inducing conditions: it may be inefficient in forming the ternary complex with ATP and DNA postulated to be the active intermediate in both strand pairing and repressor cleavage. In support of this interpretation, we have found that ATP, in contrast to the analogue ATP- γ S, promotes λ repressor cleavage much less efficiently with recA142 protein than with wild-type recA⁺ protein (<0.2 compared with 2 ng repressor cleaved per min per μ g recA protein). We presume that recA142 protein shows substantial cleavage activity with ATP- γ S because this analogue, unlike ATP, interacts essentially irreversibly with recA protein (unpublished experiments) and thus overcomes the reluctance of recA142 protein to form the active ternary complex.

The ATPase activity of the recA430 protein is only slightly more sensitive to ionic strength than the wild type (Fig. 2), presumably corresponding to its nearly normal activity in genetic recombination.

These experiments provide further direct evidence that cleavage of repressors by recA protein is the mechanism of repressor inactivation in induction. Because the recA430 protein supports recombination but not λ repressor inactivation *in vivo*, induction cannot result from the activity of recA protein as

Fig. 2 Sensitivity of ATPase activity of mutationally altered recA proteins to ionic strength. The DNA-dependent ATPase activity was measured as described previously⁴, except that the concentration of recA protein was 100 μ g ml⁻¹ and the time of incubation was 30 min. Activities measured at 0.04 M NaCl were: recA⁺, 0.31 μ mol min⁻¹ mg⁻¹; recA430, 0.30 μ mol min⁻¹ mg⁻¹; recA142, 0.39 μ mol min⁻¹ mg⁻¹.

a recombination enzyme. Our results argue against models that postulate that the interaction of λ repressor with DNA (or a recA-DNA complex) is sufficient to promote inactivation of λ repressor in the absence of cleavage²⁴.

Besides their defect in λ repressor inactivation, recA430 bacteria also fail to carry out other recA-dependent processes, such as amplification of recA protein and radiation mutagenesis^{17,25}. We suggest that these defects arise at least in part from the inability of recA430 protein to inactivate the *E. coli* lexA protein, which is thought to be a repressor of the recA gene. The lexA protein is cleaved by recA protein⁸ in the conditions we have described for λ repressor inactivation; this supports the model that recA protein amplification occurs when lexA protein is cleaved in inducing conditions by recA protein present at a low basal level. Failure of recA430 protein to cleave lexA protein would thus prevent amplification of recA protein. The inability of the recA430 cell to be mutagenized by UV light could result from its failure to induce genes required for UV mutagenesis that are repressed by lexA or are regulated by other proteins sensitive to cleavage by recA protein. This is supported by the discovery of Kenyon and Walker¹⁰ that numerous *E. coli* genes involved in DNA repair are repressed by lexA and require recA function to be induced; these might include genes required for UV mutagenesis. Although the possibility has not been tested, it is likely that a third recA-dependent activity, lethal filamentation, is defective in recA430, as this process is also thought to result from inactivation of lexA protein by recA protein^{9,26}.

We thank N. L. Craig and E. M. Phizicky for advice and discussions, N. L. Craig for performing some preliminary experiments, A. J. Clark, R. Devoret, D. Botstein, D. Mount and K. McEntee for bacterial strains, and V. Vogt for criticizing the manuscript. This work was supported by NIH grant GM21941 and by a NIH Career Development Award to J.W.R.

Table 1 Spontaneous and mitomycin C induction of λ in recA lysogens

Strain	No. of infectious centres per ml of culture	
	Spontaneous	Mitomycin C treated
recA ⁺ (λ ⁺)	1 $\times$ 10 ⁶	1 $\times$ 10 ⁹
recA12(λ ⁺)	<10 ¹	<10 ¹
recA142(λ ⁺)	5 $\times$ 10 ⁵	7 $\times$ 10 ⁴
recA430(λ ⁺)	2 $\times$ 10 ² (clear)	2 $\times$ 10 ² (clear)

Cultures were grown in minimal medium¹³ at 37 °C to 5 $\times$ 10⁷ cells per ml. Portions of each were grown a further 90 min in the presence and absence of 5 μ g ml⁻¹ mitomycin C, treated with chloroform and titred. Phage from the recA430(λ ⁺) culture made clear plaques, indicating that they were derived not from induction but from growth following mutational alteration of the repressor. Bacterial strains have been described elsewhere¹³, except the recA430 strain JM776, which was obtained from R. Devoret. recA12 is a standard RecA⁻ mutation.

Nitrogen fixation gene (*nifL*) involved in oxygen regulation of nitrogenase synthesis in *K. pneumoniae*

Susan Hill, Christina Kennedy & Eugene Kavanagh

Pennsylvania 19122, USA

The enzyme complex nitrogenase, which reduces N_2 to NH_4^+ , involves two redox proteins, both irreversibly damaged by O_2 (ref. 1). Enzyme activity therefore requires anaerobic conditions, a source of reductant and a large amount of ATP (~16 ATPs per N_2)^{2,3}. In both aerobic and facultative anaerobic N_2 -fixing bacteria, nitrogenase synthesis is regulated by O_2 and NH_4^+ , but in the aerobes there are also processes to protect the enzyme from O_2 damage^{4,5}. The mechanisms of repression by O_2 and NH_4^+ seem to be independent in the organisms so far examined^{6–8}. In the facultative anaerobe, *Klebsiella pneumoniae*, O_2 was shown to repress nitrogenase synthesis in an NH_4^+ -constitutive strain⁸. The fusion of the *Escherichia coli lacZ* gene into each transcriptional unit of the nitrogen fixation (*nif*) gene cluster in *K. pneumoniae* has facilitated studies with O_2 , because expression from the various *nif* promoters results in an O_2 -stable product (β -galactosidase). Notably, the *nifHDK* operon (the nitrogenase structural genes) was more sensitive to O_2 repression than the *nifLA* operon (regulatory genes)⁹. The characterization of mutants, reported here, indicates the involvement of a *nif*-regulatory gene product in the mechanism of O_2 control of nitrogenase synthesis.

The *nif-lac* fusions constructed by Dixon *et al.*⁹ with phage Mud(Aplac), in which *lac* is expressed from *nif* promoters, could not be directly used for the isolation of regulatory mutants, as this phage can re-transpose to new locations at high frequency (about 10^{-4} per generation; R. Dixon, personal communication). Therefore our approach was guided by the following argument. All previously described *nifL* mutations (except *nifL2265*) have been shown to be polar on the *nifA* gene¹⁰, the product of which is required for expression of all other *nif* transcriptional units⁹. *NifL2265* showed a partial trans dominance to pRD1 (ref. 11) (a plasmid carrying the entire wild-type *nif* cluster) which is consistent with a modified *nifL* gene product acting as a negative effector. Also, reversion to *Nif*⁺ by strains carrying Mu insertions in *nifL* probably occurs by the imprecise excision of Mu, implying that *nifL* product is not necessary for nitrogenase synthesis¹⁰. Hence revertants of *nifL*

Fig. 1 Influence of DOT on synthesis of *nifH* ($\blacktriangle$), *nifD* ($\bullet$), *nifK* ($\circ$) and *nifJ* ($\triangle$) gene products in the wild-type UNF50231 (a, b) and the mutant CK400 (c) strains. Results show the extent of *nif* gene product synthesis in organisms exposed to O_2 , expressed as a percentage of that occurring in a parallel culture in N_2 . Synthesis of *nif* polypeptides was quantified as the proportion of total polypeptide synthesized, and in cultures in N_2 the initial proportions for each *nif* product ranged as follows: *nifH*, 0.07–0.19; *nifD*, 0.05–0.13; *nifK*, 0.05–0.10; and *nifJ*, 0.02. Total protein synthesis was not markedly affected by exposure to O_2 . Similar experiments were performed on strains UN4357 and UNF753 and *nif* polypeptide synthesis after about 2 h exposure to 0.5% DOT compared with that occurring in N_2 was respectively as follows: *nifH*, 85 and 76%; *nifD*, 96 and 72%; *nifK*, 30 and 36%; and *nifJ*, 180 and 78% (similar results were obtained for strain UN4374); these values are significantly higher than the ones for the wild type shown in b of 35, 33, 12 and 13% for *nifH*, *nifD*, *nifK* and *nifJ* polypeptides respectively. In all experiments cultures were derepressed in an NH_4^+ -free medium²² in N_2 at 29°C. A 20-ml sample was transferred anaerobically to the N_2 -flushed oxystat vessel, equipped with a calibrated O_2 electrode mounted in a side arm and a magnetic stirrer. Immediately after transfer air was slowly introduced into the N_2 supply to the vessel until the desired DOT was reached (never taking longer than 12 min), when the oxystat (Western Biological) was switched on. The DOT value, maintained ($\pm 20\%$) by control of the gas mixture, occasionally drifted, but the time during which the DOT fell below 0.25% (the lowest DOT tested and found to repress nitrogenase synthesis) never exceeded 8% of the total time of an experiment. A control 20-ml sample was stirred in N_2 in a vessel similar to and alongside the oxystat vessel in a water bath maintained at 30°C. Samples (1 ml), removed at time intervals, were labelled with ^{14}C amino acids and protein subsequently analysed and quantified by SDS-polyacrylamide gel electrophoresis and densitometry of autoradiograms as described previously⁸.

mutants might yield strains in which the *nifA* gene product is synthesized but *nifL* gene product is inactive or lacking. Thus we screened *Nif*⁺ revertants of strains carrying mutations in *nifL* for the failure of O_2 to repress synthesis of nitrogenase polypeptides.

Initially we investigated the influence of dissolved O_2 tension (DOT) on nitrogenase synthesis in wild-type strain UNF 50231. As expected, a DOT of 0.5%, which inhibited expression of β -galactosidase in strains carrying a *nifH::lac* fusion, repressed synthesis of nitrogenase polypeptides, as did a DOT of 0.25% (Fig. 1a, b). Besides the products of the *nifH*, *nifD* and *nifK* genes, the rate of synthesis of the *nifJ* gene product also declined (Fig. 1b).

A *Nif*⁺ revertant (strain CK400) derived from a *nifL* point mutant (*nifL2265*) showed some escape from repression when exposed to 0.5% DOT. The kinetics of nitrogenase polypeptide synthesis in 1% DOT. (Fig. 1c) confirmed that O_2 repression

was less severe than in the wild-type strain UNF50231 (Fig. 1a, b). Two other *Nif*⁺ revertants (UN4357 and UN4374; W. J. Brill, unpublished), derived from two strains carrying *Mu* insertions in *nifL*, behaved similarly (see Fig. 1 legend) and synthesis of the *nifJ* product also escaped repression in all three *Nif*⁺ revertants (see Fig. 1 legend).

Both the *Nif*⁺ and O₂ constitutive properties of the revertant CK400 were due to a second mutation (*nif2400*) mapping within the *nif* region; a His⁺*Nif*⁺ transductant (UNF753) of a (*his-nifM*) deletion mutant infected with phage P1 propagated in CK400 showed escape from O₂ repression (see Fig. 1 legend). To facilitate further physiological and genetic experiments, the *his*-linked mutations in CK400 were transduced into both *nifH::lac* and *nifN::lac* fusion strains. As expected, for both fusion alleles β -galactosidase activity could be detected by blue colour formed by transductants growing on NH₄-free X-gal plates incubated in air (see Fig. 2 legend), and derepression of

Fig. 2 Genetic mapping of O₂ constitutive *nif* mutations. *a*, Current map of the *nif* genes^{10,23,24}. The lines beneath the map indicate probable transcriptional units and the arrows show the direction of transcription. *b*, The O₂ constitutive *nifH::lac* strains described in the text were made His⁺ and used as recipients in phage P1Cmclr100- or P1Cmclr100-mediated transductions from the set of His⁺ *nif* deletion mutants^{10,24} shown above. His⁺ transductants were selected and scored for *lac* expression on solidified NH₄⁺-free medium²² agar plates containing 30 μ g X-gal (5-bromo-4-chloro- β -D-galactoside) and 50 μ g serine per ml incubated at 29 °C in air; the mutants appeared blue whereas wild-type *nifH::lac* recombinants were colourless on aerobic plates. Possible wild-type transductants were always checked for retention of *nifH::lac* on anaerobic X-gal plates where they turn blue. If wild-type recombinants appeared among transductants, then wild-type DNA corresponding to the position of mutations responsible for O₂ constitutivity was not deleted from the donor deletion strains. If no such transductants appeared, then the mutations lie within the deleted *nif* segment. The number of transductants needed to be scored for *lac* phenotype (~400) to detect any wild-type recombinants was indicated from a similar deletion mapping experiment with a strain carrying the *nifL2265* allele in which 3.5 and 0.5% of His⁺ transductants were *Nif*⁺ using the *nif8755* and *nif8081* deletion alleles, respectively. In the pairs of deletion mutations marked (1) and (2) the relationship between the *his*-proximal ends is uncertain. The *his*-distal end of *nif8081* is near the *nifAL* intergenic region and probably within *nifL* as no *nifA* mutations have been found to map in the deletion interval defined by the ends of the *nif8081* and *nif8755* mutations. The placement of *nifL2265* within this deletion interval conflicts with other reported mapping experiments^{10,24}; however, repeated experiments where His⁺ transductants were scored for *Nif*, rather than being directly selected on NH₄⁺-free medium which is less efficient, consistently gave this result. The *nifT*⁻ mutations T1 and T2 were derived from strains Kp5161-3 and Kp5160-3, respectively^{13,25}. NT, not tested.

Fig. 3 Influence of an anaerobic to aerobic shift on the expression of histidase in the wild-type strain KG7035 (triangles) and the mutant UNF753, described in the text (circles). Cultures were grown in anaerobic conditions (closed symbols), and when the total protein concentration had reached 120 μ g ml⁻¹, indicated by the arrow, the culture was divided and half was transferred to an aerobic environment (open symbols)¹⁹.

β -galactosidase also occurred in liquid NH₄-limited cultures either maintained in a DOT of 0.5% or bubbled with air (Table 1). In contrast, the parent fusion strains were colourless on aerobic X-gal plates and failed to derepress β -galactosidase in 0.5% DOT or air bubbling (Table 1). The apparent insensitivity of β -galactosidase derepression to O₂ in the *nifH::lac* fusion strain carrying the *his*-linked mutations in CK400 was not due to an altered respiratory activity; the potential respiratory rate¹² and the O₂ demand in a DOT of 0.5% were the same in the mutant and parent strains (data not shown).

Three other suspected *nif* regulatory mutations including a previously mentioned *Nif*⁺ revertant of a *nifL::Mu* strain (UN4357) and two mutants designated '*nifT*⁻'¹³ also allowed synthesis of β -galactosidase in air when linked to *nifH::lac* or to *nifN::lac* (Table 1). Significantly NH₄⁺ repressed *nifH::lac* and *nifN::lac* in all four mutants, and O₂ repression was restored in each *nifH::lac* strain by the introduction of the plasmid pRD1 (Table 1).

The blue phenotype on NH₄⁺-free X-gal indicator plates incubated in air was used to locate the *nif2400* and the two *nifT*⁻ mutations, and deletion mapping experiments (Fig. 2) indicate that all three mutations lie within the *nifLA* operon and probably within the *nifL* gene. The *nifT*⁻ mutants were isolated as *Nif*⁺ colonies from a glutamine synthetase mutant with impaired regulation for *nif* and *hut* (histidine utilization)¹³. Hence the *nifLA* operon seems to be involved in the control of *nif* expression by both O₂ and, as suggested previously⁹, the regulatory proteins of nitrogen assimilation¹⁴.

Several enzyme systems in the Enterobacteriaceae are apparently regulated by O₂ (refs 14–18) and in *K. pneumoniae*, *hut*¹⁹ and *nif*⁸ are controlled by both O₂ and NH₄⁺. We therefore examined the effect of the *his*-linked mutations in CK400 on *hut* expression; in both wild-type and mutant strains, O₂ was needed for histidase derepression (Fig. 3). Furthermore, these mutations did not alter the transient influence of O₂ on glutamine synthetase levels¹⁹ (data not shown).

Thus five different strains had *nif* mutations that relieved O₂ repression of the *nifHDK* and, where tested, the *nifEN* and the *nifJ* transcriptional units. In at least one of the strains (CK400) O₂ regulation of another operon outside *nif* was unaffected. The mutations mapped in the same deletion interval that includes the *his*-proximal end of the *nifL* gene. The *trans* dominance of

NH₄⁺-grown cultures were suspended in an NH₄⁺-free medium and β -galactosidase derepression was followed as described previously⁹. Cultures were maintained in 0.5% DOT as described in Fig. 1 legend. ND, not determined.

* Strain UN4357 is a Nif⁺ derivative of strain UN2464 carrying *nifL5037::Mu*¹⁰.

wild-type *nif* and the relative insensitivity to O₂ of *nifL* expression⁹ suggest that the *nifL* product is involved as a negative effector in the O₂-regulatory mechanism specific to nitrogen fixation. Conversion to a negative effector may involve processes associated with O₂ metabolism rather than the direct interaction with the O₂ molecule. The mechanism of action of such a negative effector could be: (1) to prevent *nifA* expression; (2) to inactivate the *nifA* product; (3) to bind at each *nif* operator/promoter; (4) to promote *nif* mRNA breakdown; (5) to prevent *nif* translation; or (6) to promote *nif* gene product breakdown. The first seems unlikely because in strains carrying a *nifA::lac* fusion (where *nifL* is expressed) β -galactosidase derepression was not inhibited in 0.5% DOT (unpublished results). The sixth is improbable as synthesis of a hybrid polypeptide is unlikely in strains carrying the *nifH::lac* or the *nifN::lac* transcriptional fusions^{9,20,21}.

'Lipidic particles' are intermembrane attachment sites

THE nature of lipidic 'particles' and 'pits' in freeze-fracture replicas of liposomes has been much debated. Recently, Miller¹ presented arguments that the particles and pits represent conical deformations of membranes, rather than inverted micelles sandwiched between membrane leaflets—a model repeatedly suggested by Verkleij *et al.*²⁻⁴. We have also observed lipidic particles and pits in liposomes of mixed egg phosphatidylcholine (PC)-soybean phosphatidylethanolamine (PE)⁵ and mixed PC-PE-cardiolipin, and our results essentially agreed with those of others¹⁻⁴. Moreover, we have more convincing evidence for the deformation model as presented below. The evidence has led us independently to arrive at a similar model⁶ to that proposed by Miller.

We have obtained cross-fractured profiles of the particles and pits in multilamellar vesicles. As shown in Fig. 1a, most of the remaining halves of the fractured particles and pit are seen as interlamellar contact points, although a few single particles (open arrows) are also observed. The profile of the lipidic particle is clearly conical, with the base extending to 200 nm. They are considerably larger than the mean size of proteinaceous intramembranous particles, as seen in Fig. 1b. Here, in a PC-PE vesicle containing human erythrocyte membrane protein, large conical lipidic particles are clearly seen at the fracture line as contact sites between adjacent membranes. Proteinaceous particles are hemispherical with diameters of ~10 nm. As the lipidic particles and pit are really cusp-shape distortions, they should be named as such instead. When multilamellar vesicles containing <30% PC in PE were quenched at room temperature, rows of cusps on the fractured faces were frequently observed. However, cusps are not found in large single lamellar vesicles (verified by negative staining) of the same lipid mixture. This provides independent evidence that intermembrane attachment is required for the formation, stabilization and alignment of the cusps. Our results give definite support for the cusp model¹ in preference to the inverted micelle model².

Fig. 1 Freeze-fracture electron micrographs of multilamellar vesicles of 25% PC in PE (a), and with added crude human erythrocyte membrane protein (smaller particles) extracted with Triton X-100 (b). Lipidic particles and pits are seen as intramembrane attachment sites in cross-fractured areas (arrowhead), some of which have developed extensive contacts (solid arrows). Open arrows indicate occasional conical particles on one bilayer alone. Experimental procedures are given elsewhere^{5,6}. Scale bar, 500 nm.

VERKLEIJ AND DE KRUIJFF REPLY—We believe that 'lipidic particles' represent inverted micelles formed either within a single bilayer^{1,2} or at the nexus of intersecting bilayers during fusion of membranes³⁻⁵. We have presented^{2,3} evidence for this interpretation and

against the lipidic particles being local bilayer curvatures as inherent to the intermembrane attachment side (IMAS) model as proposed by Miller⁶ or the similar cusp model proposed by Hui and Stewart in their letter. These arguments and new facts supporting our hypothesis can be summarized as follows:

(1) The crucial point ignored by the IMAS model is that the lipidic particles have been exclusively observed in lipid systems in which at least one of the lipid species prefers the hexagonal phase II (H_{II}). In this latter phase the lipid molecules are cone shaped and oriented with their polar head group towards an aqueous channel of a small radius. Any model of the lipidic particle must take into account this favourable organization of H_{II} -type lipids, a criterion met in the inverted micelle model. This requirement, however, is not fulfilled with the IMAS model. For instance, in the cardiolipin-lecithin system⁶, cardiolipin will be present at the top of the strongly curved bilayer where it can only fit if the molecules have an 'inverted cone' shape. However, cardiolipin assumes a cone shape in the presence of Ca^{2+} .

(2) In line with this argument, a direct morphological association has been observed between the H_{II} phase and the lipidic particles^{4,7}, indicating a close relationship of these structures. Furthermore, we have found in some systems^{3,7} three-dimensional arrays of lipidic particles which probably represent an agglomerate of inverted micelles. An analogous example of structural relationships between micellar and hexagonal phase can be found in another area of lipid polymorphism in that lipids can adopt both micellar and hexagonal H_I phases in water, as, for instance, does lysophosphatidylcholine⁸.

(3) In the IMAS model, the bilayer must be strongly curved as the lipidic particles can be very small (60-130 Å in diameter)². Such a strong bilayer curvature is energetically highly unfavourable because the minimum curvature of the bilayer in the most strongly curved system (sonicated vesicles) is at least 250 Å in diameter.

(4) The IMAS model ignores the extensive ^{31}P NMR studies on the lipidic particle-containing systems^{2,9}. The profound hysteresis of the isotropic peak in the ^{31}P -NMR spectrum of these systems can be best explained by a model in which inverted micelles are located in rows at the fusion site of two bilayers¹⁰.

In conclusion, we feel that these arguments strongly suggest that lipidic particles represent intrabilayer inverted micelles. Also, the observation that in systems such as that described by Hui and Stewart the particles are relatively large and cone shaped can be interpreted as the

presence of inverted micelles at the fusion site of two well separated bilayers¹¹.

Fossil charcoal and the palaeoatmosphere

IT has been proposed by Cope and Chaloner¹ that oxygen levels in palaeoatmospheres may be assessed by the presence or absence of charcoal in the geological record. Although oxygen is required for burning, it is not necessary for charcoal formation. When wood is subjected to high temperatures, oxygen-bearing gases are evolved, yielding an oxygen-depleted graphitic network (charcoal)². Charcoal formation is favoured by low oxygen concentrations at the solid surface and forms in anoxic conditions at temperatures above 200 °C. In the remote past, however, heat from wood fires, sustained by atmospheric oxygen, was probably the dominant agent for charcoal formation. Thus, the coupling of atmospheric oxygen concentration to charcoal formation may not be as direct as has been proposed.

That the occurrence of charcoal is determined by the oxygen concentration required for carbon monoxide or methane to burn, as Cope and Chaloner presume, has not been demonstrated. Depending on configuration, ignited wood samples may not continue to burn in atmospheres containing as much as 13-21% oxygen³. At lower concentrations the most likely source of heat for charcoal formation would not be available.

It is not known whether palaeoatmospheric pressures were identical to present-day values. The proportion of oxygen required for ignition depends on the pressure⁴, but the dependence has not been investigated for wood. If inert gas is added to air, as in submarines, the partial pressure of oxygen and consequently

respiration are unaffected, but the proportion of oxygen may be reduced sufficiently to prevent a match from burning⁵.

While applauding the cross-disciplinary approach of Cope and Chaloner, we caution that the effects we have described should be considered before this potentially valuable probe of palaeoatmospheric composition be used. With refinement, this might be extended to explore fascinating problems, such as atmospheric implications of expanding Earth models and the effects of oxygen and carbon dioxide partial pressures on photosynthesis⁶⁻⁸ in the past.

CHALONER AND COPE REPLY— Although we are aware that charcoal may be produced in a variety of physical conditions, we must stress that the theme of our letter was to examine the palaeoatmospheric implications of our studies of the widespread distribution of charcoal (fusinite) in the geological record. We did not attempt to present a comprehensive survey of the conditions of charcoal formation.

In the natural environment, charcoal may be produced in conditions of both pyrolysis and combustion, but the mechanisms for charcoal formation are few. First, basalt laval flows are known to engulf vegetation and subject the included woody tissues to pyrolysis, transforming these into charcoal¹. Second, in swamp peat accumulations, local temperature rise caused by exothermic decomposition reactions may initiate smouldering which could produce charcoal. Third, and most important, combustion of vegetation by forest fire can result in the production of large volumes of charcoal as a residue. It is the last mechanism which we believe to be responsible for the generation of the greater proportion of charcoalified phytoclasts which occur in ancient sediments. Thus, our suggested implication for past atmospheric composition is not based on the range of physical conditions for charcoal production but on the

restriction (in terms of oxygen level) which can be placed on the occurrence of large-scale natural burning, that is, the combustion associated with forest fire. We placed this restriction at a minimum oxygen level of ~0.3 present atmospheric level (PAL). We acknowledge that it may be possible to produce charcoal in special circumstances with oxygen levels <0.3 PAL. However, at such levels it would not be possible to maintain the combustion mechanism for the production of the large quantity of charcoal preserved in the geological record, estimated to be 4×10^5 – 4×10^7 tons in post-Silurian rocks².

Since the publication of our letter we have learned (K. N. Palmer, personal communication) that the combustion levels of carbon monoxide and methane described in the experiments of Coward and Jones³ were based on pre-mixed flames. In conditions of natural burning the combustion is by diffusion flames, where the minimum level of oxygen required to support combustion is more likely to be ~13% (~0.6 PAL), corresponding to the lower levels of oxygen concentration in the extinction experiments of Rasbush and Langford⁴. Thus, we are able to revise our minimum estimate to ~0.6 PAL, thereby placing further constraints on estimates of oxygen concentration in post-Silurian atmospheres.

The question of increased atmospheric pressures is interesting. Since it is generally accepted that the oxygen in the Earth's atmosphere has accumulated steadily from photosynthetic build-up, any proposed models of palaeoatmospheres should set the partial pressure of oxygen at or about its present level. Presumably, for an oxygen/nitrogen palaeoatmosphere at higher than present-day atmospheric pressure, the implied increased partial pressure of nitrogen would have to be accounted for by increased rates of volcanic outgassing in the past. We do not know of any geological evidence to support or reject this type of model, and therefore can make no further comment on this aspect. In the absence of such data we can only assume that past atmospheric pressures were similar to those of the present day. In such conditions we offer the occurrence of charcoal in the sedimentary record as a valuable geological indicator in any proposed palaeoatmospheric models.

BOOK REVIEWS

Doing things in the public interest

Eric Ashby

IT TAKES courage to write a book called *Implementing Public Policy*. The author walks in the footsteps of some very distinguished stylists: Bentham and Bagehot in the last century, Wheare and Aron in this century. It was Bagehot who made the point that success in public policy "depends on a due mixture of special and non-special minds — of minds which attend to the means and of minds which attend to the end". Since Bagehot's time the means have become more sophisticated and the end more controversial. The "due mixture" of special and non-special minds sometimes fails to produce the desired result. As a rule the special mind produces a rational case, based on hard data; the non-special mind employs what is called political judgement, which is just a dignified way of saying "hunch". Lord Salisbury, writing over a hundred years ago, made the point so well that there is no room for improvement: "... you should never trust experts. . . . They all require to have their strong wine diluted by a very large admixture of insipid common sense".

Ruth Levitt's book is a variation on this theme. The merit of her book is that she eschews vague generalization about how a decision to do something in the public interest becomes transformed into something actually done in the public interest. Instead she selects a specific example of public policy and uses this as a paradigm for public policy in general. Her specific example is policy for pollution. It is an apt choice: all political parties agree that it is a good thing to abate pollution, so the issue is not bedevilled by party politics. The means for abating pollution are highly technical and cannot be left to politicians or bureaucrats; the "due mixture" has to include scientists, economists and lawyers. And the end, though not entirely free from controversy, is not obscured by ideologies. The choice of pollution, therefore, clears the ground of several difficulties.

Ruth Levitt's technique is to dissect the *Control of Pollution Act, 1974*, and then to examine its implications in four case-studies: toxic waste disposal, the EEC directive on bathing water, noise abatement, and industrial air pollution. In fact — and Ruth Levitt makes this clear — these case-studies involve not only the *Control of Pollution Act* but other laws as well. She describes, with abundant references to recent literature, how the control of dumping of toxic wastes arose in response to sensational reports in the mass media, not in response to the considered recommend-

Implementing Public Policy. By Ruth Levitt. Pp.213. (Croom Helm/Biblio, Totowa, NJ: 1980.) £11.95, \$30.

ations of a committee appointed to examine the problem by the Ministry of Housing and Local Government. The advice of the special mind was disregarded. It was "insipid common sense" on the part of the non-special mind which, in 1972, hustled a Bill through Parliament in record time to control poisonous waste.

Section 17 of the *Control of Pollution Act* is intended to supersede this hasty legislation; but action on this was delayed for over six years, partly because the special minds could not define precisely what toxic waste was. At long last, on 17 November 1980, regulations to control special waste were laid before Parliament. They illustrate one of the themes of Ruth Levitt's book: the difficulty of getting unambiguous and politically viable advice from the special minds. The regulations proscribe the uncontrolled dumping of wastes "dangerous to life". And how do you think "dangerous to life" is defined? Waste is dangerous to life if "a single dose of not more than five cubic centimetres would be likely to cause death . . . if ingested by a child of 20 kilograms' body weight". It is no wonder that there has been a prayer against these regulations in the House of Lords, where the criterion of dangerous-to-life was ridiculed in a spate of not-so-insipid common sense (one noble baroness called it "cock-eyed").

Ruth Levitt's second case-study is another example of the mismatch between the specialist and generalist ingredients of a political decision. The EEC's policy is to harmonize environmental laws in the member nations; so the Commission issues inflexible directives which are intended to apply from the tip of Scotland to the tip of Sicily (and now to the isles of Greece). The directive on bathing water, obviously drawn up with an eye to a crowded resort on the tideless Mediterranean, prescribes mandatory values for some dozen parameters that have to be measured regularly, especially where "the concentration of bathers exceeds a mean value of 10,000 persons per linear kilometer". If the state of British bathing beaches were a hazard to health, such a draconian system of monitoring might be justified; but there is no evidence whatever to support the view that the very great cost of monitoring bathing beaches in Britain according to this

directive is justified. Yet it is now Community Law; an example of policy-making just for the sake of policy-making.

The other two case-studies are equally illuminating. Policy on noise abatement, like policy on the deposition of toxic waste, is hampered by insufficient technical knowledge. Policy on industrial air pollution is not hampered in this way but it is misunderstood. The achievements of the Alkali and Clean Air Inspectorate are in fact one of the great success stories in the control of pollution. But there has never been adequate communication between the Inspectorate and the public. There is provision in the *Control of Pollution Act* (sections 79–83) to empower local authorities to keep registers, open to public inspection, with particulars of industrial emissions. A Royal Commission, a committee set up by the Clean Air Council, and sundry groups of environmentalists have urged that the public have a right to know what is in the air they breathe, but practically nothing has been done; an example of another point Ruth Levitt makes, that there is a gap — sometimes a deliberately unbridged gap — between the passing of a law and its implementation.

The case-studies are valuable and, on the whole, accurate. (Some of Ruth Levitt's statements are not, in my view, correct, but it would be quibbling to dispute them.) What is disappointing about the book is its neglect of the historical dimension of pollution policy, and the omission of any reference to studies on similar public policy done in the USA and Canada. The purpose of the case-studies is to illustrate the general pattern of decision-making for public policy. But this pattern cannot be understood if it is observed without reference to its evolution. Thus the present interpretation of the formula "best practicable means", discussed in Chapter 7 of the book, makes little sense if one does not take account of the early use of the formula in the Towns Improvement Acts in the early 1800s, the criticism of these by de la Beche and Playfair in their pioneer report to the government in 1846, and the new interpretation given to it by the Alkali Inspectorate in the 1870s.

As for reference to work on the other side of the Atlantic, I think Ruth Levitt's concluding chapter on effective public policy would have been greatly improved if she had taken account of the work done by Dorothy Nelkin and her associates in Cornell. Ruth Levitt mentions the role of

public opinion in agenda-setting, but she barely mentions the implications so perceptively analysed in *Technological Decisions and Democracy* (see *Nature* 280, 849; 1979) and other papers by Nelkin.

There is still great confusion about how public policy is made. The present demand for public participation in policy about the environment makes it very important that this confusion should, as far as possible, be cleared away. Ruth Levitt's book is a

serious and useful contribution toward this end. But, as the author herself says in the preface, her idea has not been to make judgements, but rather "to observe, clarify and draw attention to relevant detail". This is what she has done. □

Molecular genetics: a language to be learnt

Jiří Novotný

Evolution and Variation of Multigene Families. Lecture Notes in Biomathematics, Vol. 37. By Tomoko Ohta. Pp. 131. (Springer-Verlag: 1980.) Pbk DM 19.50, \$11.50.

GALILEO Galilei said that mathematics is the language in which God wrote the book of nature. Most of science seems to substantiate this idea, but there are exceptions. The whole field of chromosomal DNA study, for example, presents us with a conspicuously non-quantitative picture. Although this feature may contribute to its present-day popularity, it is also rather disturbing. It signals that our contemporary knowledge of gene and chromosome organization (to say nothing of chromosome evolution) is far from a real understanding and is merely superficial at best.

Only partly is this situation due to a lack of quantitative information. Since the advent of DNA cloning and sequencing, volumes of such data are emerging almost daily. What we seem to be lacking, however, is quantitative *understanding*. Quantitative data are no more useful than qualitative if we do not know what they mean and in what context to understand them. The uniqueness of Ohta's book lies in the fact that, for the first time, it outlines a quantitative theory of what happens with the genomic DNA in the course of time.

The book is brief, informal and although it contains some (rather unimportant) errors, it is appealing in its sincere endeavour to provide us with a unified and thorough explanation of diverse phenomena: genetic correlation among and within multigene families governed by unequal crossing-over, amino acid sequence variation of immunoglobulins, amino acid site linkage disequilibrium, gene conversion, accumulation of non-functional genes. This is a difficult goal; in consequence the book is sometimes hard to follow. Compared to the intricacy of the subject itself, it is nevertheless a condensed and understandable presentation which is well worth reading. Ohta's work goes far beyond the pioneering studies of Smith

(*Science* 191, 528-535; 1976) and others in that it deals not only with the evolution of a single chromosome but also with the sexual gene exchange in a population. A key notion of the theory is the identity coefficient: the probability of two genes of the same multigene family being identical by descent. Several different coefficients are defined and compared to analyse different levels of the genome; conclusions drawn from their comparison are indeed interesting. Particularly original and innovative is the analysis of immunoglobulin V regions. The within-species and between-species coefficients are computed separately for the framework and hypervariable sections of the V genes and shown to vary correlatively. Another part of the book gives a non-traditional discussion of a notorious issue, the question of V gene families and subfamilies and their interrelation in the course of evolution.

I have no doubt that anybody who is interested in molecular evolution will find this book stimulating and useful. □

Great balls of fire?

E. Philip Krider

Ball Lightning and Bead Lightning: Extreme Forms of Atmospheric Electricity. By James Dale Barry. Pp. 298. (Plenum: 1980.) \$29.50, £18.59.

THE remarkable phenomenon of ball lightning has both frightened and fascinated mankind for centuries. A typical ball lightning is a mobile sphere, about the size of an orange or grapefruit, which is produced during a thunderstorm and which remains luminous for one or more seconds. *Ball Lightning and Bead Lightning* is the second book to be published about this subject by Plenum in the past ten years. The first book, *The*

Nature of Ball Lightning by S. Singer, was an attempt to integrate many of the previous papers on ball lightning, both observations and theories, that have appeared over the past several hundred years.

This second work by J. D. Barry reviews the known physical characteristics of ball lightning that have been deduced from visual observations and laboratory experiments, and then attempts to deduce other characteristics and properties which are consistent with these observations. One chapter is also devoted to a discussion of bead lightning, a more familiar phenomenon but one which is still poorly documented in the scientific literature.

The book begins with a brief description of normal lightning and an assumption that ball and bead lightning do indeed exist. Chapter 2 lists all known references to bead lightning, and then presents all published photographs of this phenomenon together with a critical evaluation of their interpretations. The remaining six chapters are devoted to a review of the characteristics of ball lightning, a presentation and critical evaluation of all published photographs that have been reported to be of ball lightning, a review of the laboratory experiments which have attempted to reproduce the natural event and a comprehensive bibliography.

The book is well written and complete at a qualitative level. The principal deficiencies are in the review of normal lightning characteristics and the discussion of bead lightning — the characteristics of normal discharges are quite important if one is to evaluate production mechanisms or if one wishes to compare ball characteristics with a normal channel. No values are given for leader and return stroke currents or their statistics; there is no discussion of continuing currents; and the electric power and energy dissipated by normal flashes is not considered. There is no presentation of time-resolved photographs, which almost always show the streaks of persisting luminosity that may well be a short-duration form of bead lightning. The suggestion that bead effects are most commonly observed during cloud-to-cloud discharges (p.11) is contrary to the cloud-to-ground emphasis in works previously published by lightning researchers. There is also no discussion of whether a simple projection of the three-dimensional channel tortuosity toward or away from the observer could explain the beaded appearance of, say, a long-continuing current.

Despite these shortcomings, the book is a valuable introduction to a fascinating subject and will certainly stimulate research in this area. The collection of over 50 photographs and a bibliography of over 1600 entries are truly exceptional and will serve the scientific community well for years to come. □

Cooperation in limnology, a further achievement of the IBP

C.M. Yonge

The Functioning of Freshwater Ecosystems. Edited by E.D. Le Cren and R.H. Lowe-McConnell. Pp.588. (Cambridge University Press: 1980.) £40, \$95.

THE objective of the International Biological Programme was the furtherance of our understanding of the biological basis of productivity and its relation to human welfare. The study of productivity involved the organization of international studies on land, in the sea and in freshwaters. The last-named posed the greatest problems, both because previous international studies had been slight and because conditions in such waters range so very widely — from oligotrophic highland lochs to tropical alkaline lakes containing dense but specifically restricted algal populations which support equally specialized fish and bird populations.

Because it involved the stimulation of self-financing local enquiries, no section of the programme demanded greater organization. The eventual world-wide participation is indicated in the maps which adorn the end pages of this book which, following earlier publications concerned largely with methodology, represents the final outcome of the freshwater programme or, more concisely, IBP/PF. Under the overall supervision of the Director General, Dr Barton Worthington, especial responsibility rested with the full-time coordinator, Dr Julian Rzoska, to whose dedicated activities, including the particularly close involvement of eastern European countries, this impressive volume is a tribute.

As Professor Livia Tonelli, the last of a number of convenors, writes in the Introduction, "This book is the result of years of a corporate effort by many scientists all over the world to advance the knowledge of production limnology". The truth of this statement is borne out when it is realized that it represents the combined contributions of no less than 43 authors reporting from the 93 widely scattered sites. Not only was interest so widely stimulated but important bilateral projects came into being between such widely separated countries as West Germany and Brazil, France and Chad, Japan and Malaya, and Britain and Uganda.

Freshwaters vary widely in character and consequent productivity; they are also quickly and often profoundly influenced by local human activities with consequences ranging from total toxicity to extreme eutrophication. Yet they also have great potential, realized most fully in Southeast Asia, for the production of fish and prawns for human consumption.

All means of control, alike against damage and towards increased productivity, depend on basic understanding of prevailing conditions. It is this that is the

theme of the book. The chapters range from discussion of the effects of physical and chemical variables to analysis of primary and secondary production. Studies on the significance of organic matter and decomposers are followed by chapters on trophic relationships and efficiencies, then come others dealing with estimations of productivity and consideration of the value of dynamic models of lake productivity. The final

chapter by G.G. Winberg provides a most interesting summary of the results of Soviet freshwater studies.

The overall result with its final 66 pages of references is a volume of unique value to all limnologists and one of the major achievements of the International Biological Programme. □

Wooldridge and Linton re-viewed

F. W. Shotton

The Shaping of Southern England. Institute of British Geographers Special Publication, No 11. Edited by David K. C. Jones. Pp.274. (Academic: 1980.) £14.60, \$34.50.

THIS book was commissioned by the Institute of British Geographers to celebrate the fortieth anniversary of the publication of Wooldridge and Linton's *Structure, Surface and Drainage in South-East England* (IBG, 1939). In a preface and ten chapters, eleven authors are involved, some of them more than once. This assembling of the latest opinions of geomorphologists on the evolution of the topography of their own terrain, namely the Thames Basin, the Weald and the Hampshire Basin, will be appreciated by geologists and geographers from a much wider area. The evolution of the form and drainage of this part of England was argued about long before Wooldridge and Linton, as K. Clayton points out. The value of *Structure, Surface and Drainage* lay less in its conclusions than in the way it combined meticulous field observation with scientific interpretation and thus steered geomorphological thought to its present position.

Although it is stated that the book is a memorial to Wooldridge and Linton, only four chapters examine their conclusions critically. Two of these, by D. K. C. Jones and R. J. Small respectively, deal with the development of the landscape during the Cainozoic era, and although Small adds the words "an alternative interpretation" to his title, it is more of an alternative to Wooldridge and Linton than to Jones. Both authors reject two of the main tenets of the original interpretation, which postulated a late Oligocene or early-Miocene "Alpine storm" of earth deformation with subsequent tectonic quiescence while the land surface was reduced to a peneplane, and a marine invasion (the so called Calabrian or late-Neogene transgression) to a height of about 200m. Instead they envisage a

succession of deforming pulses from the early Eocene onwards, with concurrent erosion or deposition.

Two other papers, by C. A. Baker with D. K. C. Jones and by C. P. Green and D. F. M. McGregor, deal with the diversions of the course of the Thames during the Pleistocene. These I found less satisfying, for although the authors differ from several points of the original interpretation, they also reveal how much still remains unresolved. On the age and origin of the Chiltern Drift, surely pre-Cromerian but not inevitably a till, there is no clear consensus.

The other contributions are not so closely related to Wooldridge and Linton but are no less interesting because of that. They deal with the origin of the sarsens, the residual deposits of the North Downs, the palaeohydrology of the Kennet Valley and the effect of periglacial weathering on Chalk. A final chapter by C.P. Green describes the development of geomorphology as it is now understood and practised, and discusses its probable future. Green points out that modern geomorphology, combining as it does the study of land form and drainage, the physical processes by which these are developed, stratigraphy, sedimentology, palaeoenvironment reconstructions and relative and absolute chronology, was taken over by geographers from the geologists. It gives no pleasure to me to read (and half admit) that this was due to "the relative lack of interest in the Quaternary among British geologists". In fact Wooldridge, acknowledged as one of the great pioneers in modern geomorphology, was, by training and early employment, a geologist. Green's chapter emphasizes that geomorphology is now neither simple geography nor geology but a hybrid of both, biology also providing a formative influence. The subject is truly scientific and very much a part of earth science. □

F. W. Shotton is Emeritus Professor of Geology at the University of Birmingham.

CORRESPONDENCE

Continued from page 356

of confusing the origins with the content of a scientific theory⁴. Any student of sociology or philosophy of science is likely to be intrigued by the social framework of the emergence of sociobiological theory over the last decade and its relationship to the New Right ideology⁵. But having explored that link, it is the task of critics of sociobiology to expose what they see as its methodological, *internal* inadequacies (for example, refs 6 and 7).

If sociobiologists want to avoid the charge that they believe that biology is destiny, they should beware of telling magazines that they know "why we do what we do" or entitling their books *The Selfish Gene*, *The Inevitability of Patriarchy* or *On Human Nature*. The trouble is that they want to have their cake and eat it. They imperialize the human sciences (*vide* the first paragraph of *Sociobiology, The New Synthesis*) and are embarrassed by the outcome.

This is why the final chapters of Dawkins' or Wilson's books are so confusing. Having set out the inexorable destiny of genetic predispositions to xenophobia, aggression, patriarchy or whatever, they invoke the possibility of a human conscious prospect of overcoming these predispositions. As Dawkins puts it in his letter, with respect to philandering males "many humans (have) some at least momentary intention of overcoming their polygamous tendencies. Many even succeed in this". For Wilson euphenics may overcome any "hereditary tendency" to acquire xenophobia. Free will, intentions and wishes (or Dawkins' memes) like the US cavalry, come galloping over the horizon in the nick of time to rescue us from our genes.

But *where* does our free will, etcetera come from? How can we be *both* genetically programmed robotic DNA survival machines and have the extraordinary capacity to transcend these programs? The truth is that sociobiological determinism, when challenged, collapses into the weakest sort of Cartesian dualism. For consistent materialists — like Gould, whom Dawkins quotes, and, I hope, myself too — we must argue that wishes, intentions etc. are as much, or as little, "given" by our genes as any other aspect of our human existence. The interesting thing about humans is that the fact that we can change what we do is as much part of our biology as how we do what we do. To give the example used in my review of Wilson — if humans were quadruped and not biped, their social arrangements would be different; that humans are biped is genetically "given", therefore the human social order is genetically given. The point is that such genetic syllogisms are boringly uninteresting about either any of the crucial aspects of differences *between* human societies or the changes that occur *within* any given society. They neither explain nor predict apartheid in South Africa, cultural revolutions in China, Born Again Christianity in the United States, the welfare state or its dismantling under Mrs Thatcher in Britain, still less any of our individual proclivities.

On such questions then, biology has to be silent. It is because self-styled sociobiologists are *not* silent (I challenge anyone to read *The Selfish Gene* and come away *without* a clear impression of Dawkins' views of what biology

has to say about the Welfare State, sexual mores or microeconomics) that their work both trivializes important social and biological questions and is so amenable to neo-Nazi and New Right ideology.

Conservation sites

SIR — The attack on conservation sites by Muir (*Nature* 12 March, p.82, 173), apart from ignoring that the scientific value is by no means the only value considered by conservationists, is based on several unacceptable assumptions.

In implying that conservation sites are primarily for the preservation of rare species Muir ignores the fact that most have been primarily designated in order to conserve particular vegetation types, associations of organisms, natural or semi-natural ecosystems. The argument that "value to science of any objects or phenomena lies not in themselves but in the information they yield to study. Once this information is recorded and published whatever value remains in the objects or phenomena is of no value to science" is ridiculous on two counts.

First, he specifies no criteria of "value" that are meaningful. He merely transfers the problem of what he means from conservation sites to published information about them. Even if one disregards this problem one is left, on his own arguments, with a strong case in favour of conservation sites. Ecology is still a young science and it has hardly scratched the surface in its study of the vast majority of ecosystem types. The rate of ecological advance does not compare favourably with the rate of loss of certain habitat types. There are, as yet, no vegetation types or ecosystems whose study has been exhausted to the extent that they are of no further interest to ecologists!

I am responsible for the "sites of special scientific interest" that make up the Malham Tarn Nature Reserve, one of the best documented nature reserves in the country. Its scientific documentation started with observations by John Ray in 1671 and has rapidly accelerated since 1947. We now know enough to realize that it will require much more study than that already accomplished before any scientist would be other than foolish to suggest the site was of no further interest to science.

The tragedy of the present rate of loss of sites of special scientific interest is that we know so little of what is being lost. What little we do know strongly suggests that the Nature Conservancy Council have correctly identified the sites of greatest interest to science apart from them being those necessary if we are to achieve the conservationists' aim to convey the maximum diversity of wildlife into the next century. The conservationist is not, as Muir implies, trying to halt evolution. He is

primarily concerned with the perpetuation of a diversity of habitat types. A variety of forest organisms depends on a variety of forest habitats — regardless of the rates of evolution of their organisms.

DMSO and immunity

SIR — The observations of Pestronk and Drachman¹ that dimethyl sulphoxide (DMSO) reduced anti-receptor antibody titres in experimental myasthenia gravis in rats are of considerable interest. The authors conclude: "It seems likely that DMSO might also be effective in ameliorating other active humoral immune responses. If so, DMSO may provide an effective new treatment for immune diseases mediated by autoantibodies." Lest this statement lead once more to proclamations of DMSO as a wonder drug, several important points need an answer.

The LD₅₀ of DMSO by intraperitoneal (i.p.) injection is between 10 and 11 per kg for rats and mice. Pestronk and Drachman injected 1.0 ml of DMSO into rats daily for 14 days. Assuming a body weight of 250 g for a rat the dose of DMSO for each rat would be approximately 4 g per kg, or 36 per cent of the acute LD₅₀. The injection (i.p.) of this amount of DMSO into rats and mice produces a number of pharmacological and biological effects including an increase in peripheral blood pressure, changes in the oxygen levels, probable anoxia in the spleen and hypothermia^{2,3}. In mice the level of hypothermia is severe, with rectal temperature reaching 33.5°C and recovery after a single injection of DMSO (4.5 g per kg) takes more than 6 h. Hypothermia represents a generalized but reversible toxicity. Many chemicals when injected at levels of approximately 20–40 per cent of the LD₅₀ produce similar effects.

Thus the clearly demonstrated effects of DMSO in decreasing antibody titres illustrated by Pestronk and Drachman may not be specific. In any event the possible therapeutic usefulness of a chemical effective at doses so close to the LD₅₀ is unlikely to prove clinically acceptable.

3. Ashwood-Smith, M. J. *Int. J. Radiat. Biol.* **34**, 101 (1961); *Ann N. Y. Acad. Sci.* **141**, 45–62 (1967).

SIR — The comments of Professor Ashwood-Smith should serve as a useful reminder that the pharmacological actions of dimethyl sulphoxide must be carefully examined. The mechanism of action by which the drug suppresses anti-acetylcholine receptor antibodies in the experimental animal model of myasthenia gravis is not yet understood. Moreover, the reduction in serum antibody levels must be taken into account as a possible undesirable effect if the drug is contemplated for other clinical applications.

Per Ardua ad Astra (et Terram)

One swallow does not make a summer, but for people yearning to see the winter end, the sight of even a single swallow is bound to seem a cheerful omen. This is the spirit in which the managers of the United States National Aeronautics and Space Administration (NASA) will be glued to their television screens for the next few days, waiting to see whether the new reusable spacecraft, the shuttle, will succeed. With luck, the first version of the shuttle (called Columbia) will be launched on Friday this week, roughly two years later than first planned. Soon afterwards, it should be clear whether the spacecraft has found its way into an orbit about the Earth. Just over two days later, it may have found its way back again, to an airstrip in California. That is the plan. NASA officials will not be the only people biting their nails through this tense period. Several crucial scientific enterprises, the Large Space Telescope in particular, hang on the success of the shuttle. So do several important technical projects, the further development of the international telecommunications network for example. And while it is by no means clear what the Pentagon has in mind for this new means of putting things and people in orbit, the chances are that a success for Columbia this weekend will spark off a round of vigorous jockeying for priority in the launching timetable among the potential users. So much is easily predictable.

It is therefore churlish but also necessary, even at this late stage, to raise the question of what happens if Columbia fails. Ordinarily, if the shuttle were a more conventional spacecraft, the consequences of failure would be negligible. The managers at NASA would bite their lips, utter whatever stoical comments the circumstances of failure required — and set to on the readying of the next spacecraft from the production line. If Columbia fails, they will no doubt follow the same tack but with less conviction. With the budget for the next fiscal year still enmeshed in Congress, it is unlikely that they could escape the thorough investigation of the whole shuttle programme that they have managed to avoid in the past two years. And even if the first flight of Columbia is a success, it is now clear that the development of the shuttle has been too much of a scramble for comfort.

Of the problems that have beset (and delayed) development,

the most serious is that concerned with the device for protecting the spacecraft from heat on reentry into the atmosphere. Recurring troubles with the ceramic tiles intended to accomplish this would have been comic if they were not also almost tragic. It has been forgotten that the tiles are a makeshift substitute for the wonder alloys foreseen when the shuttle was originally conceived of a decade ago, and which have not materialized. The other glaring deficiency in the development programme is the lack of flight experience. A single launching from the back of a Boeing 747 can hardly command confidence. By contrast, recurring problems with the rocket motors, which may nevertheless turn out to be disastrous, are largely a monument to the American passion for optimizing everything — never use a rocket motor off the shelf if there is a chance that a purpose-built motor might be slightly more efficient seems to be the motto. If Columbia fails this weekend, these questions are certain to be reopened.

Others than NASA officials should therefore keep their fingers crossed. The whole device may have been an imperfectly considered technological leap in the dark, but success promises a quantum jump in the utilization of orbits about the Earth. The planned reduction of cost (by roughly a factor of ten for unit mass placed in an orbit) is only a part of the promise. The possibility that the shuttle may be a means of maintaining and repairing satellites already in orbit is potentially more important. Whatever the outcome of this weekend's experiment, there is therefore the strongest possible case for NASA to spend a substantial part of its hard-won budget on a more satisfactory solution than the present of the heat-shielding problem. That cannot be a simple task. Heat-shields based on thermal insulators whose surfaces ablate at high temperatures, widely used to protect the warheads of long-range missiles, are plainly unsuitable for spacecraft intended to be used repeatedly. Solid insulators intended to get rid of heat by radiation are even more susceptible than others to destruction by thermal shock. But mechanical cooling systems based on circulating fluids are probably impractical — their mass would be too great. NASA has already let one contract, seeking an alternative solution. It should quickly cast its net wider. For the shuttle, for all its defects, it is the best American spacecraft in sight.

Who, not Congress, should police fraud?

How often do scientists cheat? How seriously, in the process, is the scientific literature corrupted? And what, if anything, should be done to put a stop to the occasional transgressions that come to light? The United States Congress (see page 435) should not be surprised that it failed to answer these questions in its brief inquiry last week into a few of the cases of wrongdoing that have come to light in the past few months. On the other hand, there is no reason why the research establishment should resent the inquiry or even fear that the outcome will be a novel, intrusive and probably unworkable system of regulation imposed from Washington. There is no reason to suppose that Representative Albert Gore's subcommittee seeks to be a kind of arbiter of ethics in the research laboratory or that it plans to recommend some central system of regulation. The most sinister of the plausible motives for last week's inquiry is that the subcommittee, which plans next to take up more general (and important) issues such as the propriety of arrangements between academic scientists and commercial companies in the field of genetic engineering, the adequacy of agreed procedures for experiments with human subjects and the

like, is seeking to demonstrate at the outset that not all scientists are, like Caesar's wife, above reproach.

The committee's inquiry would have been more productive if it had more clearly thought through the problem of malfeasance in research before dragging its impressive collection of witnesses to Washington last week. It should not have confined its inquiry to biomedical research, and it should have distinguished more clearly between the different kinds of misdemeanours that have from time to time become open scandals. The committee (and those who gave evidence last week) should also have had the wit to recognize that any formal central system for the prevention of misdemeanours is likely also further to inhibit freedom of access to the scientific literature. Journals and their referees are already sufficiently aware of the dangers of having wool pulled over their eyes. More restraint would diminish the chance that heterodox ideas would find their way into the light of day and further tip the scales against innovations.

Plagiarism, the most flagrant of misdemeanours, is paradoxically not as serious a cause for concern as some pretend.

The activities of Dr E.A.K. Alsabti which came to light last year (*Nature* 285, 429 and 286, 437; 1981) were a flamboyant demonstration of how a person can make a mark in the literature with the help of a photocopying machine and a little ingenuity in rewriting the titles of other people's articles. Of necessity, however, success (if that is the word) requires that the plagiarist should be satisfied with publication in relatively obscure journals and that he should pass off as his own only uncontroversial or even dull observations by other people. Journals are not well-placed to spot this kind of transgression — even though some of Alsabti's published papers should have set off alarms in the editorial offices of the journals in which they appeared. But even the most ingenious plagiarist cannot expect a long career. However obscure the journal in which he publishes, and however uninteresting the topic, systematic retrieval systems are now good enough to ensure that those working in the field, including the authors whose work has been plundered, will recognize what has happened within a year or so. In more active fields of research, detection is likely to be even faster. So much is clear from the sensation last year in which one of Professor Philip Felig's collaborators at Yale University was accused of having stolen some text from a paper he had seen as a referee: not unnaturally, the plagiarizing paper was sent to the original authors for review and the whistle was quickly blown. Out-and-out plagiarism, then, is likely to be a nuisance only for librarians and bibliographers. It is exceedingly improbable that working scientists will be misled. And the penalties for the transgressors are severe — they are as a matter of routine expelled from the scientific community.

The falsification of data is necessarily a more troublesome misdemeanour. If a person chooses to send for publication a set of data which is the product of imagination and not experiment, there is very little that journals and their referees can do to identify the deception. Nor would it help if would-be authors were required to send with their manuscripts copies of their laboratory notebooks (even though journals often require that authors should submit evidence to support puzzling conclusions, for example when there are doubts about the statistical analysis of raw data which do not form an integral part of a paper intended for publication). In the ordinary course of business, journals and their referees are not as competent as a reasonably competent investigator to make an assessment of what is involved. The laboratory bench has something in common with the confessional. It must be supposed that a person is telling the truth. If he is not, the penalties are severe, as Dr John Long, dismissed in January 1980 from the Massachusetts General Hospital (see *Nature* 289, 227; 1981) for falsifying published data, has found to his cost.

Unfortunately, cases of falsification rarely emerge as clearly as this. The scientific literature is replete with records of observations which cannot be accommodated within the accepted framework of understanding but which are much more often the result of faulty techniques and mistaken interpretation than of deliberate falsification. And, no doubt, hidden in this mass of data are observations representing genuine challenges to accepted theories. It would be catastrophic if journals habitually declined to give house-room to data that could not be accommodated within the existing body of received wisdom. Although, on such occasions, journals have a duty to enquire closely into the methods by which data have been obtained, in the last resort it is essential that uncomfortable data should be published, not suppressed. If some small part of these data should be fabricated — and it is more likely that false data will be used in the support of orthodoxy, which is just as dangerous — that cannot be the end of the world.

In the nature of things, it is exceptional that a single set of data can overthrow an accepted theory or sustain one that should be discarded. Even dramatic events such as the observation in 1921 that the images of distant stars were deflected at the limb of the Sun as predicted in 1917 by Einstein's theory of gravitation did not still (and have not stilled) arguments about the validity of that monumental work. Similarly, Dr Joseph Weber's entirely well-intentioned claim (in 1968) that gravitational waves had been

detected by equipment based at the University of Maryland and the Argonne National Laboratory, although published in respectable journals (*Physics Review Letters* for example), carried little conviction even though it stimulated several attempts to repeat the observations of a phenomenon that should be observable, although not as strongly as Weber claimed. For what it is worth, the more recent observations by Steele and Gorczynski (see *Nature* 289, 678; 1981) of the inheritance of acquired immunological characteristics in mice deserve a place in the scientific literature even if, in the long run, their interpretation turns out to be different from that now given to them. At least where data bear on general understanding, witchhunting for fabricated data is likely to do more harm than good. Time will tell what data make sense, while the scales are already too powerfully weighted against the heterodox.

So is there nothing for the US Congress to be alarmed about? That, unfortunately, is not the case. Last week's inquiry produced some disturbing evidence of deliberate falsification in the trial and assessment of new drugs. No doubt from the best of motives (a concern that individual patients should have the advantage of the newest drugs), physicians are tempted to include in clinical trials people not eligible under the protocols laid down. Such deceptions will usually lead to the underestimation of the value of a new drug or other treatment, and thus risk the deprivation to future patients of valuable procedures. The safeguard, however, lies in the hands of those who supervise clinical trials — given the understandable temptation, why not demand authenticated medical histories of the patients included in them? Falsification of data bearing on the safety of new drugs, frequently (in the United States) produced by independent contracting laboratories, is potentially a more serious and intractable problem, but here again the remedy is accessible, and administrative. In such circumstances, bodies such as the Food and Drug Administration should (and frequently do) demand access to original laboratory records. Moreover, the agency has sufficiently competent technical staff to carry out a proper assessment of such data. In any case, the laboratories concerned, knowing that their reputations are at risk, have a vested interest in accurate reporting. It should not be beyond the wit of regulatory agencies to ensure that they are not wilfully misled.

So should Representative Albert Gore's committee conclude that there is nothing to be said? That is what Dr Philip Handler was suggesting last week. Unfortunately, that is too simple a view. Although the scientific community is enviably free from wrongdoing, at least as compared with other professional communities (lawyers or politicians, for example), it is too simple to suppose that the peer review system can be relied upon, at least in the long run, to root out all deception. One obvious snag is that acclaimed success, even if based on the over-interpretation of data, tends to breed more success. Grant-making bodies would be less than human if they were able to avoid all such traps. The past few months have also uncovered disturbing evidence that investigators holding substantial research grants are relatively immune from the scientific criticism of their close colleagues, and that they may also be so heavily engaged in the administration of a research programme (including the search for further grants) that they have little time to give to the detailed assessment of the data produced by research programmes in which they are titularly involved. Many of those to whom these descriptions apply will no doubt have mended their ways after learning of the tragic object lessons of the recent past. For the ultimate safeguard of the authenticity of scientific data rests not merely on the peer review system (whose critics necessarily lack first-hand knowledge) but also on full and frank discussion within individual laboratories. The benefits, too often denied, are not merely that a tiny proportion of unauthentic data will struggle with more difficulty into print but that laboratories will in general be made more productive and creative. It would be seemly if the subcommittee in its report urged such steps. It would be ridiculous to go further, and to ask that there should be some formal external process for demonstrating what is already self-evident — that the research profession is as much like Caesar's wife as can be expected.

Universities complain at Pentagon policy

Restrictions on foreign students cause alarm

Washington

Government interference in academic research, ostensibly to control the export of technical data, has stung the presidents of five top universities to protest. The Pentagon is seeking to limit the involvement of foreign research students on certain projects. The universities have also protested, in a letter to Defense Secretary Casper Weinberger and Secretary of State Alexander Haig at attempts to restrict the publication of unclassified research sponsored by the Pentagon.

The university presidents express concern about guidelines issued recently by the department in which defence officials suggest that universities should limit the involvement of foreign students in research related to the development of very high speed integrated circuits (*Nature* 289, 736;1981). They complain that at least one university has been told by the Department of Commerce not to allow certain foreign scholars to participate in its sponsored research activities — a reference to the Export Administration Regulations restricting the transfer of technical data and equipment to communist nations. More action along these lines is expected.

The signatories to the letter are Donald Kennedy, president of Stanford University; Marvin L. Goldberger, president of the California Institute of Technology; Paul E. Gray, president of the Massachusetts Institute of Technology; Frank H. T. Rhodes, president of Cornell University; and David S. Saxon, president of the University of California. According to the text of the letter, not yet officially released by the universities, the full-scale classification of research, where appropriate, is "far preferable" to the application of "restrictive and virtually unenforceable regulations" to universities. For those university activities which remain unclassified, they add, the government should give up all attempts to apply the restrictions until broader issues — which include a possible conflict with the first amendment to the constitution, guaranteeing freedom of speech — have been resolved.

Two sets of export restrictions lie at the heart of the universities' concern. The first is the International Traffic in Arms Regulations, introduced by Congress in the early 1970s to limit the export to any country of technology (including technical knowhow) of potential military value. The

second is the Export Administration Regulations of the Department of Commerce, aimed at limiting the export of technology of commercial value to certain countries, particularly those in Eastern Europe.

Confusion has arisen in universities and scientific organizations — and in the federal agencies themselves — largely because of the difficulty in drawing a clear line between basic knowledge obtained by scientific research and results which, although still described as "basic", have been developed with a particular long-term military or commercial application in mind.

Last year, for example, the regulations were invoked by the Department of Commerce to prevent scientists from Eastern Europe from attending an open meeting on computer bubble memories organized by the American Vacuum Society, one of more than 40 scientific societies which have since applied for exemptions from the export controls for future scientific meetings on the grounds that, since these are open meetings, they should not be considered to involve the transmission of "secret" data.

The concern expressed by the five

university presidents, however, applies more specifically to the conditions that must be observed by scientists in US universities and research institutions, and their freedom to publish the results of their research or to communicate it to non-American scientists through seminars or even informal discussions.

Officials at Cornell University, for example, said last week that in one recent instance the Department of Commerce had placed conditions on a foreign scientist's visit, restricting his access to research at the university, which it had not been prepared to accept, and the visit had been cancelled. In another instance, a research contract proposed by the Department of Defense specified that, although the research was to be unclassified, the department's permission was required before any results were published — a condition which many universities, such as Stanford, say they would find unacceptable.

The five university presidents point out that although the regulations have existed for several years, only recently have they begun to be applied to "traditional university activities". The new interpretation could result in restrictions which

Gowans washes hands of Rothschild

New York

Recent changes in the organization of medical research in the United Kingdom mean that the customer-contractor basis proposed by Lord Rothschild between the Medical Research Council (MRC) and the Department of Health and Social Security (DHSS), "has now been abandoned", Dr James Gowans, director of MRC, told an audience at the Rockefeller University in New York last week.

Gowans — Rothschild off his back

Describing the British approach to medical research funding, Dr Gowans said that after the customer-contractor relationship was introduced in 1972, with substantial funds being transferred from MRC to DHSS, only a handful of new contracts had been awarded. "It became apparent that the customer-contractor

principle was not applicable to medical research, certainly not on the scale envisaged by Rothschild.

Following further discussions, the Rothschild arrangement had been abandoned and the money previously transferred to DHSS had been transferred back to MRC. "We are now back in the situation that we were in before 1972", Dr Gowans said, adding that "to a scientist it is gratifying", since many members of the scientific community had argued strongly against Rothschild's ideas when they first appeared.

MRC and DHSS "both now realize that fundamental solutions to problems such as cancer and coronary heart disease cannot be conjured up by the use of contracts. It is not possible to use bureaucratic devices to accelerate the rate of scientific progress", he added. As part of the new arrangements, MRC had also agreed to undertake more health services research, since the council had been told that much of the work carried out under that heading was very important but not very well done.

Mistakes had arisen in government science policy through a failure to distinguish between areas of research — such as cancer research — where the basic principles were not known and the science could not be substantially accelerated merely by providing additional funding, and areas where the scientific principles were known and additional support would provide more substantial results.

David Dickson

would conflict with the fundamental precepts that define the role and operation of the American university system, they say. Strict interpretation, coupled with the severe criminal penalties that they contain, would be even more restrictive than direct classification of the research.

In response to the letter, whose addressees also include Mr Malcolm Baldrige, the Secretary of Commerce, the three federal agencies involved have apparently told the universities that they are looking closely at the problems raised, but it is expected to be several weeks before a formal reply is agreed upon.

The potential impact of the export control regulations on the academic community is already being discussed by an *ad hoc* committee set up last month by the National Academy of Science's Committee on Science and Public Policy.

The rules are also being closely studied by the National Science Foundation. Dr Donald Langenburg, the Deputy Director, says the foundation is "deeply concerned" about the potential impact of export controls on research, adding that it is "critical" to the freedom of scientific exchange that these are kept to a minimum consistent with foreign policy and national security objectives.

The growing tension between the academic community and the federal agencies over the interpretation of export restrictions is precisely the type of problem for a presidential science adviser, still absent from the White House. **David Dickson**

DNA research guidelines

Dutch get tough

Brussels

The publication by an *ad hoc* committee of revised safety rules for recombinant DNA research has raised some grumbles in Dutch industrial circles. By and large the new guidelines, the conclusions of a year's study of the risks of gene manipulation, follow closely those set by the National Institutes of Health in the United States. But while other European countries are moving towards a relaxation of the rules, the Dutch have tightened up the restrictions on research with pathogenic microorganisms.

Companies such as Unilever and Gest-Brocades, which are carrying out research into the industrial applications of bioengineering are, however, more frustrated about the administrative checks on research. In the Netherlands, DNA research is first vetted by the *ad hoc* committee, although there is no legal obligation to register the research. Local authorities then have the last word over individual experiments and any new research laboratories.

It is up to the committee, the local authority and university advisory groups to interpret the guidelines as they see fit. Industry complains that it is unnecessarily

restrictive to ask permission to carry out each individual experiment. Unilever has taken some of its projects to Belgium and Gest-Brocades has switched some of its resources to its UK laboratories. In the meantime both expect to wait at least a year for approval on new laboratories. The companies feel that local government authorities are much harder on industry than on universities.

The Netherlands is now thought to have the toughest rules in the world. Public distrust of DNA research caused four members of the *ad hoc* committee to abstain from the final vote on the new guidelines on the grounds that there should be a study of the impact of genetic engineering on society as a whole.

The European Community's Economic and Social Committee is taking the same option. Last July the European Commission brought out its own recommendation on the registration of DNA research, which stressed that over the past three years it had become clear that DNA research is not as dangerous as was originally thought. However, before agreement is reached between the Economic and Social Committee and the European Parliament, a public workshop is to be held in May that will bring together representatives from a cross-section of society to discuss the economic, social and ethical implications of such research.

The Commission's recommendation, if it is adopted, would do little more than establish common definitions and provide the basis for a consensus on registration procedures. However, many researchers increasingly feel that arguments about risk assessments are academic. The bulk of research is carried out in the lowest risk class and very rarely in PIII containment conditions. Thus, the slightly stricter rules proposed by the Dutch are expected to have little impact. **Jasper Becker**

Solar Polar mission

Joint project saved?

The European Space Agency (ESA) is "cautiously optimistic" that something will be salvaged from the International Solar Polar Mission, although in a less ambitious form than originally envisaged. The two-spacecraft mission to study the polar regions of the Sun was threatened last month when the US National Aeronautics and Space Administration (NASA) announced that, to meet budget cuts, it would not be building its spacecraft.

Although it is unlikely that NASA will restore the mission to its original status, angry protests and diplomatic pressure by European embassies in Washington seem to have prompted a compromise. According to ESA, that might involve NASA building a cheaper spacecraft — costing \$40 million rather than the \$100 million originally planned.

Under such a scheme, NASA's space-

Congress redispenses

Washington

A congressional subcommittee has now prepared the ground for restoring the United States half of the Solar Polar Mission. Last week, the space science subcommittee of the House of Representatives Science and Technology Committee voted to make cuts elsewhere in the National Aeronautics and Space Administration's (NASA's) budget for the fiscal year 1982; these cuts made it possible for the subcommittee to restore money for projects such as the Solar Polar Mission (which was given an additional \$15 million) without exceeding the total for the NASA budget of \$6,700 million proposed by Mr Reagan. Since the rearranged budget package will not incur additional costs, House Democrats are hopeful that the pro-space science subcommittee of the Senate Commerce Committee, which votes later this month on NASA's authorization, can also be persuaded to accept reinstatement of the solar spacecraft, perhaps on a smaller scale. **David Dickson**

craft, which would lose a de-spun platform carrying a solar coronagraph for direct imaging of the Sun, would be almost identical with ESA's. Two similar spacecraft would allow measurements of spatially and temporally resolved dynamic phenomena, which would not be possible with only one.

ESA's dismay at NASA's decision to abandon its part of the mission was largely due to the fact that it had already spent most of the money for its spacecraft in European industry. NASA, on the other hand, had delayed building its craft after the planned launch date of the mission was put back last year. If NASA is willing to compromise, ESA will agree to a further launch delay to 1986, even though it would increase the costs. The precise details of the compromise will have to wait until Dr James Beggs, NASA's new director, is installed. **Judy Redfearn**

Biotechnology

Canada takes stock

Washington

After six months of intensive study, a task force set up last summer to look at the development of biotechnology in Canada has recommended that the Canadian government should establish a ten-year National Biotechnology Development Plan, with a budget that would rise to about \$50 million a year. Most of this money would go on research and training; exploitation would remain for the private sector, which the task force recommends should receive significant tax incentives.

The task force was set up by Canada's Minister of State for Science and Technology, Mr John Roberts, and was

headed by Dr Maurice Brossard, director of research at the Institut Armand Frappier in Laval, Quebec (*Nature* 285, 431; 1980). Although acknowledging that the extra financial investments which it recommends would be a significant financial burden at a time of fiscal constraint, the task force says that the proposed sum "is a very conservative estimate of required federal expenditure".

Three factors are listed which make this expenditure important — the wide range of potential applications of biotechnology, the importance of biotechnology to Canada's future industrial development and "the almost complete lack of existing Canadian biotechnological capability".

On the last of these, the report is disarmingly frank. The second section of the report, "Biotechnology in Canada: An overview", contains two short paragraphs which refer to a "practically non-existent biotechnological industrial base", a rapidly shrinking federal government research capability and a highly fragmented and unfocused university research effort.

To correct this situation, the task force suggests that the graduate and postgraduate training programmes of the Natural Sciences and Engineering Research Council and the Medical Research Council should be increased by \$3 million and \$1.4 million respectively in the next financial year.

Less predictable is the proposal that Canada's immigration policies be revised "to address the immediate shortage of biotechnological skills which are in high demand worldwide".

The government is expected to endorse the proposal that commercial exploitation be achieved through tax incentives rather than direct government investment. The task force has, however, suggested direct government assistance of up to \$6 million to encourage small and medium-sized biotechnological industries. **David Dickson**

European uranium supply

Australia signs up

Brussels

A large slice of Europe's need for uranium over the next 30 years is to be met by a guaranteed supply from Australian ore. Australia and the European Atomic Energy Community (Euratom) last week initialled a draft of a joint nuclear safeguards agreement in Canberra which should enable Europe to buy uranium from Australia. Negotiations began in 1979 and the Canberra meeting was the fifth round. The agreement has been pursued with great determination by Euratom because Australia, with 20 per cent of the western world's uranium reserves, is very important to Europe's supply strategy.

The basic deal, to run for 30 years, is for Australia to guarantee supply of uranium exports in exchange for European

Community exports of nuclear technology and promises that the radioactive material will not be re-exported or used for military purposes.

Similar agreements are also being negotiated with Canada and the United States. The Canadian deal is a renewal of the 1959 agreement which expired last year and has run into difficulties on the issue of "sensitive" nuclear material (uranium enriched above 20 per cent). Negotiations to renew the agreement with the United States have been held up until the Reagan Administration is firmly in the saddle.

Negotiations with Australia went smoothly until the Australian government decided to impose new conditions. These included a commitment by Euratom member states to ensure an efficient monitoring of reprocessing techniques and to finalize an international plutonium storage programme; a promise not to use or store plutonium extracted from Australian uranium in a way that might lead to proliferation; and that the member states should ask for prior permission on a case by case basis to use the material for research or civil purposes.

In effect, then, the Australians are going further than the Nuclear Non-Proliferation Treaty. The Community negotiating team have been trying to establish precise definitions of the circumstances in which prior permission must be obtained. Does, for instance, using nuclear power to drive submarines constitute a peaceful purpose?

Full details of the new agreement, likely to be similar to the Australian deals with China and Japan, will not be divulged until the final text is agreed. **Jasper Becker**

Fraud in research

Congress asks why

Washington

Dr John C. Long, whose resignation from the Massachusetts General Hospital was forced last year after the discovery that he had fabricated research data, went before a congressional committee last week in sackcloth and ashes. The committee chairman, Representative Albert Gore, complimented him for shouldering full responsibility for his acknowledged "wrongdoing and dishonesty". Dr Long said that he liked his new job (as a surgical pathologist at a Detroit Hospital) — and that he had no plans to return to research.

Dr Long's remarkable statement was one of the few misdemeanours that the government oversight committee of the House of Representatives Committee on Science and Technology had been able to assemble for its two-day inquiry into wrongdoing in science. On the second day of the inquiry, officials from the Food and Drug Administration accused the National Cancer Institute of withholding information about the potential side effects of an anti-cancer drug it was testing. But most of the hearing was taken up with several cases of apparent fraud and abuse

that have recently emerged in the scientific literature and the public press.

The data which Dr Long admitted to fabricating were included in a paper published in the *Journal of the National Cancer Institute* (62, 787; 1979) in response to a critical comment by a referee. But Dr Long also admitted that he had concealed from his colleagues that cell lines purportedly derived from patients with Hodgkins's disease had been contaminated with other cells later shown to have been owl monkey cells (Harris *et al. Nature* 289, 228; 1981).

Nature misrepresented

Washington

In his evidence to the subcommittee, Dr Philip Felig said that two journals, one of them *Nature*, had refused to publish a letter of retraction. Dr Felig said that *Nature's* refusal to publish stemmed from a concern for the personal plight of Dr V. Soman, his collaborator responsible for an act of plagiarism who was afterwards found also to have falsified published data.

After the hearing last week, however, Dr Felig agreed with the editor of *Nature* that his evidence to the subcommittee had been misleading; that *Nature* had agreed to publish the retraction when the audit, then under way, of Dr Soman's laboratory work had been completed; and that at the time (June 1980), he had expressed himself as satisfied with this arrangement.

The chairman of the subcommittee was informed of this conclusion both by the editor and by Dr Felig, and agreed to include a note to this effect in the published record. Dr Felig's intended retraction was in respect of the paper "Regulation of the glucagon receptor by physiological glucagonaemia" by V. Soman and P. Felig, *Nature* 272, 829-832 (1978).

The force of his confession, however, was blunted by the statement by Dr Ronald Lamont-Havers, his former departmental head at the same hospital, that investigations carried out since Dr Long's departure have shown that other data, previously published, may also have been fabricated.

The subcommittee's objective last week was threefold: to estimate the frequency of wrongdoing in biomedical research, to understand the causes of such behaviour, and to decide if anything should be done.

Most witnesses agreed that falsification and plagiarism in the scientific literature is a rare but persistent phenomenon. Dr Donald Fredrickson, director of the National Institutes of Health (NIH), took some pleasure in telling the committee that Gregor Mendel's research results did not stand up to modern statistical analysis.

But even so, the Food and Drug Administration reported that it has disqualified 42

investigators from work with new drugs since 1966, when procedures were devised to deal with violations of the regulations for the administration of new drugs to patients. There have been 20 disqualifications since 1977, when a more formal "Bioresearch Monitoring Program" was set up. At NIH, Dr Raub said that rules covering the grounds on which a research scientist can be barred from receiving further funding had recently been tightened, and that, although no individual had been disbarred in the history of the institutes, at present five instances were on record where a scientist would have questions raised about his or her past conduct if a further research grant application was received.

The committee seemed to accept that known cases of falsification are the tip of only a small iceberg. The suggestion by Dr Philip Handler, president of the National Academy of Sciences, that in the circumstances the committee should turn its attention to more important problems was not, however, well calculated to win friends. The chairman of the committee put Dr Handler firmly in his place with a declaration that falsification entailed the waste of public money and damaged the public reputation of science; and that if the committee was not satisfied that the research community could police itself, it might have to recommend external regulation.

The committee found its position strengthened by testimony from Dr Alexander Capron, executive director of

the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research, who recounted the difficulties that the commission was having in obtaining details from the Department of Health and Human Services on the procedures followed in cases of suspected misdemeanour, especially in the treatment of human subjects.

Witnesses differed last week on the motives for falsification. Most of the scientific witnesses held that the pressure of competition for research grants is not an important spur to falsification, but the committee seized on Dr Long's admission that to have shared with his colleagues doubts about the authenticity of his cell cultures would have jeopardized his application for a \$500,000 research grant as evidence to the contrary.

Dr Philip Felig, professor of medicine at Yale University, was closely questioned about the relationship between senior scientists and their colleagues. A case of plagiarism in his own laboratory eventually cost him appointment as dean of the medical school at Columbia University (see *Nature* 285, 429; 1980). He acknowledged that there may be occasions when a collaborator sets out to "please" his senior colleagues, and that the dangers are especially great when the senior person has not himself developed the techniques his collaborators are using. Yale, Felig explained, has now introduced a formal procedure for the independent internal investigation of disputed research results.

Known misdemeanours

Apart from the cases mentioned in the accompanying text, the following is a list of the misdemeanours cited at last week's inquiry by the congressional oversight subcommittee.

University of Kansas (1977). Allegations by two women graduate students that a grant awarded by the National Institutes of Health for anthropological research had been wrongly used for work with human subjects, including the collection of blood samples and genetic counselling. The university established (in 1978) that the work with human subjects had not been cleared with the Institutional Review Board. The investigations (and a civil slander suit by the investigator) continue.

Boston University (1978). Allegations of the falsification of medical records of patients and certain research reports, part of a cooperative study of new cancer treatment financed by the National Institutes of Health (NIH), were substantiated by an internal investigation. The leader of the unit (Dr Marc Straus) resigned on 24 June 1978, followed by his more senior associates, and the Boston University records were expunged from the cumulative records of

the Eastern Collaborative Oncology Group. The investigation continues, but Dr Straus, then at the New York Medical College, Valhalla, was awarded an NIH grant of \$1.3 million over three years in January 1980.

University of California, Los Angeles (1979). Allegations of experimental bone marrow transplants without proper approval from the institutional review board (known as the Human Subjects Protection Committee). The investigations continue.

New York (1978). Inspection by Food and Drug Administration (FDA) revealed "persistent violation" of rules for the administration of novel drugs to human patients by the independent psychiatrist Dr Nathan Kline. Formally debarred by FDA on 13 November 1980.

FDA (various) (1966-81). Total of 42 disqualifications from access to "investigational" drugs, with 18 further cases under investigation. So far, four such investigators have been prosecuted (and one gaoled). Roughly 6 per cent of routine investigations "have led to a more in-depth review". Most violations involve lack of patient consent, inadequate accounting for drugs, violation of protocols and inaccurate (or missing) records.

UK hydraulics research

Deep water ahead

The British government's policy of "privatization" — the sale of public assets — which has already led to the sale of all but a minority stake in the British Aerospace Corporation, now threatens several research laboratories run by the Department of the Environment. The Hydraulics Research Station at Wallingford is the most immediately in danger.

The proposal to make the Hydraulics Research Station self-supporting follows a three-month market survey commissioned by the department and completed last October, in which it was suggested that a potential £1.15 million is available from the private sector. Of this, £0.2 million comes from UK markets, £0.28 million from contracts usually covered by European companies, £0.5 million from offshore projects and the remainder from increasing prices by an arbitrary 10 per cent. The present income is made up of 85 per cent from government and 15 per cent from private contracts.

The market survey suggests that although the UK market is fairly static, the potential for contracts in offshore projects and in the developing countries is considerable. However, a recent survey by the National Maritime Institute foresees a decline in offshore contracts over the next five years. There is also formidable European competition for contracts in developing countries.

The experience of private companies is not encouraging for those at Wallingford. Both the Wimpey Laboratories and the British Hovercraft Corporation have suffered severe financial difficulties. The Water Research Centre, which underwent some sort of privatization following the amalgamation of the Water Pollution Research Laboratory, parts of the Water Resources Board and the Water Research Association, is experiencing similar problems. When it was formed in 1974, the centre was seen by central government as a way of keeping small municipal water undertakings up to the mark. The civil servants involved at first rejected the plan but finally agreed on a package deal. The future of the joint enterprise seemed secure — the centre was financed by its members, with all local and municipal water authorities contributing. In the past year, however, there have been almost 100 redundancies.

Employees at Wallingford now fear that the reputation of the laboratory will be damaged. They also fear that the withdrawal of public funding will inevitably lead to a reduction of background research. However, they see advantages in some sort of halfway "privatization" which would free them from government constraints, particularly on staffing levels, and enable them to take on more contract work. The Government is now

not, however, prepared to consider such a proposal although a meeting has now been arranged for 14 April between the Central trade union and the Department of the Environment. A shadow board is to be set up on behalf of the prospective private company to explore the viability of the enterprise and to prepare employees for privatization — the target being 1 September 1981.

Sara Nash

Europe's directive on drugs

Lords back industry

Proposals from the European Commission to make it easier for entrepreneurs to buy drugs in one country of the European Community and sell them at a profit in another have met with strong opposition. The UK pharmaceutical industry and the House of Lords Select Committee on the European Communities

are at one in condemning the idea as unfair to the companies and unlikely to improve the health services in member states.

The opportunity for this "parallel importing" arises because at the moment price controls for drugs are widely different in the various member states. The European Court of Justice ruled that attempts by big pharmaceutical companies to stop parallel importing were restrictive and in breach of the Treaty of Rome.

Drug manufacturers and importers must obtain marketing authorization from national health services. To make things easier for the parallel importer in the name of free trade, the commission's directive requires the original manufacturer to make available to the importer any necessary documents relating to the specification of the batch of drug being re-sold. This type of freedom of information is anathema to drug companies which may have spent thousands of pounds in obtaining the information in the first place.

In putting the case for the industry, the Association of the British Pharmaceutical Industry (ABPI) argued that moves to bring down the general level of drug prices would not be in the long-term interest of the consumer. And the practice of parallel importing raises problems because importers may change the name and packaging of the drug, with risks that the consumer might not get the correct information about the product.

In the United Kingdom the pricing structure for drugs has kept prices relatively low. In the past few years companies have been allowed to increase prices in line with inflation but for some time "product licences" were given on condition that price increases were kept at about half that rate. As always the industry is keen to stress how expensive it is to develop new drugs and that this should be considered in pricing. So the prospect that the low-price UK market might be opened up to bulk buyers wanting to sell in countries where UK manufacturers are allowed to sell at higher prices is seen as a cause for alarm by both ABPI and the Lords Committee.

The United Kingdom is the most successful exporter in the Community, and last year the British pharmaceutical industry achieved a record £522.9 million surplus of exports over drug imports despite the problems caused by a strong pound. The Lords report sees little reason to jeopardize the well-being of a healthy industry only to give more profits to the middle-men.

The general question of bringing prices into line across the European Community will need more thought than a simple attempt to promote free trade. Both continental and UK manufacturers would favour a uniform system that is subtle enough to take account of both national and international pressures on the companies, and the particular needs and preferences of health services in the member states.

Charles Wenz

Opening up Siberia

Research in steppes

More than 400 scientific research institutes are to be involved in the Soviet Union's new "Siberia" programme which is part of a plan to give this relatively backward area an economic growth rate 30 per cent higher than that of the rest of the country.

Projects will concentrate on the energy sector, according to Academician Valentin Kaptyug, chairman of the Siberian section of the Soviet Academy, with "work of world class" on methods of obtaining synthetic liquid fuel from coal and natural gas. The Baikal-Amur Mainline railway has opened up a new zone for potential development and much of the investment will be in that area. Later more industrialization will take place around the Arctic coast, and in zones around new water resources created by the diversion southward of water from the Siberian rivers.

A food development programme includes proposals from 27 biological and research institutes for the development of new varieties of crops and livestock adapted to Siberian conditions,

Siberia, here we come

"hormonal" methods for increasing crop yields, and pest control methods aimed at leaving minimum toxic residues.

Siberia already produces 50 per cent of the oil and 33 per cent of the natural gas extracted in the Soviet Union. The extraction of fossil fuels in Siberia is expected to go on increasing up to the end of the century, so not surprisingly the new "Siberia" programme also contains work on new prospecting and surveying methods, industrial catalysts and forestry management.

Any practical benefits obtained through the new research programme will be concentrated around "technical production complexes" linking several scores of industrial enterprises. One such complex has already been established, based on the giant power stations on the Angara and Yenisei rivers.

Vera Rich

Tangled policy on drugs

Brussels

The European Court of Justice ruled in 1976 that Hoffman-La Roche were impeding free trade in refusing to give product information to parallel importers. The Italian company Centrafarm had been buying Valium in the United Kingdom and repackaging it for resale under the trivial (not registered) name "diazepam".

The latest proposals from the European Commission are another attempt to limit the monopoly power of large drug companies. Opposition to the Commission comes from most members states, and the European Proprietary Association, representing pharmaceutical companies producing drugs for general sale rather than medical prescription, spoke against the proposals at the Lords committee.

Germany, Italy and the Netherlands are considered high-price countries — on several occasions the European Commission has caught out Italy for supporting unrealistically high prices and court actions have brought down prices in Italy by about 20 per cent.

One effort by the Commission to simplify procedures was the Committee for Proprietary Medicinal Products set up five years ago. The committee can be called upon if a producer wants to put a product on the market in at least six member states, or if there are disparities in the judgements of national licensing authorities. But since it was set up the committee has examined only eight cases.

The adverse comments from the House of Lords seem certain to put another nail in the coffin of the Commission's proposal which has already been languishing for a year in Coreper, the committee of the member states' permanent representatives to the European Community.

Jasper Becker

CORRESPONDENCE

Cancer hazards

SIR — Epstein and Swartz (*Nature* 289, 127; 1981) cited our critique of the report by Bridbord *et al.* on *Estimates of the Fraction of Cancer in the United States Related to Occupational Factors*. Their citation was correct as given, but misleading without our antecedent qualifications. In general, we agree with many others who have reviewed the document that the estimates of occupationally related cancer presented there are probably substantially higher than the data support. In any event, the important question is what reduction in cancer frequency might be achieved by control of occupational exposures. Further epidemiological inquiry should improve those estimates.

Science Center,
Houston, Texas, USA

Draize test must go

SIR — The news that Revlon is to finance research into developing an *in vitro* alternative to the Draize test for eye irritancy should be welcomed by everyone, not just by anti-vivisectionists (*Nature* 19 March, p.181). The Draize test is notoriously unreliable, yet it has survived basically unchanged for over 36 years. A replacement is long overdue.

As far back as 1971 a survey of intra- and inter-laboratory variation in the interpretation of results indicated that the Draize test was inadequate for assessing eye irritancy even on a simple pass/fail situation. As a result of the study it was recommended that, failing moves to improve reliability, the test had little relevance and should be excluded in regulations as a toxicity test. Despite this, the Draize test is still the only recognized test for eye irritancy.

On scientific grounds alone, the Draize test should have been replaced years ago.

IQ put to test

SIR — In his recent *Nature* article¹ N. J. Mackintosh refers to our research demonstrating a relationship between IQ and "inspection time", the latter being a measure assumed to reflect the speed at which a person processes information.

Although we have found inspection time to be correlated with IQ, this relationship becomes statistically significant only for samples with widely varying IQ scores. The correlation coefficient of -0.92 between inspection time and IQ was obtained from a group of 10 individuals whose IQ scores ranged from 47 to 119. We emphasized that this correlation should be interpreted cautiously because of the manner in which the sample was chosen. Furthermore, this relationship was found only with respect to Performance IQ scores, as measured by the Wechsler Adult Intelligence Scale; correlations between Verbal IQ and inspection time estimates were much smaller and not statistically significant². Our study involving 48 subjects, and which found a correlation of -0.80 between Performance IQ

and inspection time³, also included retarded persons. Here again the strong correlation was the consequence of a very wide range in IQ scores. The study involved three groups, each of 16 adolescents; a retarded group where IQ scores ranged from 57 to 81, a group of nonretarded individuals with IQ ranging from 90 to 115, and a third group with scores between 116 and 130. We found no difference in the values of inspection time for the two nonretarded groups (mean = 93 ms, standard deviation = 40 ms and mean = 90 ms, standard deviation = 42 ms). Further analysis of these data (not previously published) confirms only a low correlation between inspection times and IQ for the 32 nonretarded subjects ($r = -0.23$).

At this stage of our research, it is not clear what inspection time is measuring. It is one of a number of measures⁴ developed within a model which attempts to account for capacity limitations, response bias and the caution with which a response is made⁵. The inspection time index suggests that it may prove useful for investigating what limits there are to the speed of human information processing. Insofar as it turns out to be an adequate measure of a sub-process involved in human decision making, it may conceivably be a factor in what might be termed intelligent behaviour, assuming as is widely held that this involves a speed component. To suggest more at this stage, however, seems unwarranted.

Why conserve?

SIR — Without seeking to emulate the composer Johann Joseph Fux, who "could not resist being drawn into endless polemics"¹ we feel that some of the points raised by Dr Muir² require critical examination.

The argument that a species or habitat need not be preserved after it has been "competently" investigated raises several questions. First, what criteria can be used to decide whether a particular investigation has, in fact, been competently executed? After the completion of a study by one group of investigators, will it be possible for other workers to confirm or refute their findings, or will the relevant biological phenomenon already have ceased to exist? Second, is it realistic to suppose that everything can be learned about a given phenomenon using presently available experimental techniques? Will future techniques have nothing new to contribute? Third, are biologists concerned only with documenting facts which immediately become historical, rather than remaining current?

Perhaps the most surprising feature of Dr Muir's arguments is that they are utilitarian. Their implication is that a species or habitat should not be permitted to exist for its own

sake, but only if it provides an opportunity for human exploitation. It must be unusual for a professional biologist to express this opinion.

Lamarck's revival

SIR — The following type of argument has always struck me as unfair to Lamarck and beneath the dignity of a respectable scientist. On the one hand, the emphasis of microevolution and minuteness of changes from one generation to the next, combined with extreme refinement and a plethora of sophisticated tricks (mutation, selection, drift, spatial isolation, genetic isolation, etc.) employed in defence of Darwinism and, on the other, the arrogant vulgarity in discrediting Lamarckism, for example, "why does not a woman whose arm is amputated produce one-armed children?" (ref.1), "can an animal practice being purple?" (ref.2).

The essence of the scientific argument is the validity or otherwise of the Weissman doctrine. It seems logical that resistance to transformation of somatic changes into genetic ones must be high to prevent an organism from the danger of over-reacting to environmental fluctuations and to make it maintain a certain stability. But, in view of the importance of feedback in nature, it seems unlikely that the Weissman barrier is completely leakproof under sustained nonrandom directional stress. Even from the Darwinist viewpoint such complete rigidity and unresponsiveness does not make much sense.

Whether Steel and Gorczynski³ are right or wrong is not so much important in this context. What is extremely important however, is that they are forcing the discussion onto a scientific level which it deserves.

Evolution on trial

SIR — Following the evolution trial in Sacramento, California, thanks are due to scientists who responded to requests from Mr Tyler and myself, acting as his consultant, to be available as witnesses. These were Drs C.R. Berger, B. Dalrymple, R. Dickerson, R. Doolittle, A. Kornberg, J. Kumamoto, W. Laetsch, R. Lemmon, W. Mayer, E. Olson, C. Sagan and D. Wake, evolutionists all, who generously agreed to undergo, if needed, the inevitable frustrations and delays of courtroom trials.

The next "round" will presumably be in Arkansas, where legislature passed a bill, on 17 March, prescribing the teaching of creationism.

NEWS AND VIEWS

A tropical Volute shell and the Icarus syndrome

from Jonathan C. Howard

DARWIN tells a little parable in his autobiography¹ which he learned as a very young man, before the *Beagle* voyage, from Adam Sedgwick, the Professor of Geology in Cambridge.

"Whilst examining an old gravel-pit near Shrewsbury, a labourer told me that he had found in it a large worn tropical Volute shell, such as may be seen on the chimney pieces of cottages; and as he would not sell the shell, I was convinced he had really found it in the pit. I told Sedgwick of the fact, and he at once said (no doubt truly) that it must have been thrown away by some one into the pit; but then added, if really embedded there it would be the greatest misfortune to geology as it would overthrow all that we know about the superficial deposits of the Midland Counties. These gravel-beds belong in fact to the glacial period, and in after years I found in them broken Arctic shells. But then I was utterly astonished at Sedgwick not being delighted at so wonderful a fact as a tropical shell being found near the surface in the middle of England."

The point of the parable is that science does not merely consist of making observations but also of ordering them in relation to each other. The tropical shell did not fit into an ordered scheme, and so either the shell or the scheme was wrong. Sedgwick backed the scheme against the shell and won. There would be nothing unscientific about backing the shell, but the quality of support would have to be strong in proportion to the length of the odds against it. No stone could be left unturned to verify every aspect of the find, and eventually a hypothesis would have to be formulated of sufficient generality to accommodate the coexistence of Arctic and tropical shells in the same deposits. Even then the pre-existing scheme would probably not be 'wrong' but merely incomplete. Sedgwick rather overstated the case. New, confirmed and revolutionary discoveries in science very rarely utterly degrade an existing scheme and rebuild its elements in an entirely new pattern. In biology only the theory of evolution by natural selection came close to doing this, and most of the material incorporated into

the new theory was altered only in context rather than form.

The scientific temperament varies, no doubt, along many dimensions. But certainly one of the most interesting is the dimension of credulity. How eccentric does a finding or proposition have to be before it runs off the end of your credulity scale? Are you for the shell or for Sedgwick? Incredulity was my first reaction when I heard by the usual roundabout route that Dr Gorczynski of the Ontario Cancer Institute was reporting the transmission of acquired immunological tolerance through the male. I assumed that the grapevine, with its usual capacity for decreasing the signal-to-noise ratio, had got the sex wrong. Maternal transmission would have fitted comfortably into a well ordered scheme since mother and fetus are known to engage in a rather wide-ranging immunological discourse both before and after parturition; but the grapevine had got the sex right, and here was our tropical Volute shell in the glacial gravel pit. What the grapevine did not say was anything about the genesis of the experiment, and this was a grave omission. Gorczynski's collaboration with Dr E. Steele was conducted with the specific intention of searching for paternal transmission of tolerance, under the influence of Steele's already formulated hypothesis² that RNA viruses might act as vectors for the horizontal transmission of the DNA-coded information from somatic cells to cells of the germ line. According to this hypothesis, transmission through the male is more probable than through the female because male germ cells are formed continuously throughout life.

The phenomenon became public knowledge when the experiments were first published last year³. The level at which I have heard these experiments and their sequel⁴ discussed has varied from gleeful iconoclasm, through critical scepticism tinged with curiosity, to frank disbelief. More upsetting is the charge that the data are suspect because the experiments were

designed and conducted under the influence of a hypothesis of high import. Under these conditions, so the argument runs, the eye is guided more by hope than by the ineluctable evidence of the y-counter. I assumed that this naïve folly had been killed by Sir Peter Medawar's graceful and persistent advocacy of the importance of hypothesis as a guide to useful scientific action, but under the provocation of Gorczynski and Steele's results it seems to have risen from the grave. Since Darwin is often pushed into the ring to confront Steele, I might add that Darwin unequivocally endorsed Steele's logistical procedures when he wrote⁵: "How odd it is that anyone should not see that all observation must be for or against some view if it is to be of any service".

As for the gleeful iconoclasm, it reminds me of the scornful laughter which greeted my Latin master when he muffed an easy declension. He remained an incomparably better classicist than we were. How much of neo-Darwinism are the iconoclasts prepared to throw out on the strength of Gorczynski and Steele's findings? Weissmann's doctrine of the isolation of the germ plasm from somatic influence was a brilliant hypothesis. If it had been badly wrong, genes would not behave in the elegant and predictable way that they do. In the context of Steele's hypothesis, if viral vectors are engaged in the transmission of DNA between cells, and, as implied by Gorczynski and Steele's recent paper in *Nature*⁴, are no respecters of the linkage group, we should have no loci and no alleles. The chromosomes of the germ cells would be a randomized dump of DNA sequences gathered from cells all over the body (see Darwin's *Provisional Hypothesis of Pangenesis* for a nineteenth century expression of this idea)⁶. Every time alleles behave like alleles and linkage groups behave like linkage groups it is another conformation of the generality of mendelian genetics and of the integrity of the germ line, and a further exception to the generality of Steele's hypothesis. However, since neither Weissmann's doctrine nor mendelian genetics predict Gorczynski and Steele's findings, the obligation falls on everyone concerned to find out what

Jonathan C. Howard is at the ARC Institute of Animal Physiology, Cambridge, UK.

kind of exception to the order of things these phenomena are.

It is the mixture of critical scepticism and curiosity alone that is going to resolve this matter. It is a tribute to the vigour of these faculties in the immunological community that this issue of *Nature* carries two manuscripts which go directly to the heart of the scientific problems on hand. First and foremost, are Gorczynski and Steele's results readily reproducible? Brent and colleagues (see p.508) have conducted one of the most serious attempts I have ever seen in immunology to reproduce an experimental protocol in detail. Furthermore, the analysis of the phenomenon is extended in two ways: tolerance was assessed by skin graft rejection as well as the capacity to generate cytotoxic cells *in vitro*, and repeated tests of *in vitro* reactivity were performed on individual animals. There is no escaping the conclusion that, under the conditions of these experiments, the Gorczynski and Steele result has not been confirmed. The explanation for the inconsistency between the two results is now confined to the residual procedural differences between the two series of experiments. Brent and colleagues draw attention to several such differences, only one of which is, in my opinion, important. This difference is in the cell populations used to induce tolerance in the experimental fathers. Gorczynski and Steele's tolerance-inducing protocol was eccentric in the extreme: enormous doses of cells were injected repeatedly into the fathers from birth until the end of the breeding period. Heroically, Brent and his co-workers repeated this anomalous procedure, but they made one mistake. The very first injection of cells, given on the day of birth, consisted of a total of 10^8 composed of equal quantities of bone marrow and spleen cells in Gorczynski and Steele's experiments, and 5×10^7 composed of one part of marrow to ten parts of spleen in Brent and colleagues' experiments. Brent's group is inclined to minimize the significance of this difference, but this seems a foolhardy attitude. Since there was, until Gorczynski and Steele's results were published, no reasonable expectation that any protocol would work, Brent and colleagues cannot dismiss any substantial feature of the successful protocol as insignificant. Curiosity and scepticism are, I am glad to read, carrying these authors still further to the point of reproducing even this aspect of the original protocol in their future experiments.

The importance of this difference in protocol is impossible to assess at present, but there is one crucial point which deserves more emphasis than Brent's group give to it. Amazingly, despite the ruthless régime of tolerance induction, the experimental fathers were apparently not fully tolerant by the measure of their ability to produce *in vitro* cytotoxic activity against the tolerizing parent. In Gorczynski and

Steele's experiments the tolerant fathers were shown to be as tolerant as normal F_1 hybrids. Gorczynski and Steele's *in vitro* induction system was less efficient than that of Brent and colleagues, and weak residual activity may not have been visible, but the difference between apparently fully tolerant and apparently not fully tolerant fathers cannot be considered trivial in an experiment on the transmission of tolerance. Perhaps the difference is real and important, and perhaps it too hinges on the difference in the cellular composition of the first inoculum used to induce tolerance.

When Gorczynski and Steele's first results were published, discussion among colleagues threw up two further kinds of experiment which we felt would explore the generality of the original claim. As self-tolerance is presumably an acquired characteristic, the A homozygous progeny of an $(A \times B)F_1$ father mated to an A mother might show inherited hyporesponsiveness to B alloantigens. Second, since the method of inducing tolerance used by Gorczynski and Steele was so unusual and must have resulted in a high level of chimaerism in the tolerant fathers, we wondered idly what would be the immunological behaviour of the progeny of male $A \leftrightarrow B$ embryo fusion chimaeras with extensive chimaerism in all tissues, ideally including the gonads as well. So rapid and relentless is the march of science that both our lunchtime speculations have already appeared as substantial experimental results. Hasek and colleagues⁷ have done the backcross experiment and McLaren and colleagues (including some of Brent's group) the embryo fusion chimaera experiment (see p.513 in this issue *Nature*). In neither case was any detectable level of specific hyporesponsiveness found in the progeny of the appropriate matings. Again, therefore, Steele's hypothetical mechanism finds itself narrowly constrained by results. If acquired immunological tolerance can be inherited through the male, then the conditions under which this occurs are special and not yet adequately defined. Weissmann and Mendel still provide the general case. We need an explanation for Gorczynski and Steele's tropical Volute shell, but the superficial deposits of the Midland counties are still of glacial origin.

There is much good in this fascinating transaction. A novel and imaginative hypothesis has provoked a series of experiments which would probably never otherwise have been done, certainly not with so much care. The results are conflicting, but there is a *prima facie* case from Gorczynski and Steele's two successful studies for continuing to treat the matter as being of the greatest importance. Even if it turns out, surprisingly, that both sets of positive results have some completely trivial explanation, our perspective will still have been enduringly enriched by the reminder that sex may not be the only way of trans-

ferring DNA between cells.

There is also something bad about what has happened over the past few months, which concerns the fragile and ill articulated matters of tact and style in the presentation of scientific material. Steele's book, *Somatic Selection and Adaptive Evolution*, was unlikely to have turned many heads without some truly original experimental support. It conflates an unacceptably wide variety of experimental findings into a single scheme, and fails in its obligation to apply an intensive critical appraisal in conventional terms to each set of findings in turn. The issue with which it deals, the mechanism of adaptive evolution, is not an entirely open question. Recent evidence for great complexity in the organization of genetic material shows that the beguiling simplicities of the double helix and the genetic code are probably not sufficient to explain all the properties of evolving systems; but this does not mean that all that has gone before can be discarded. Natural selection remains in the pre-eminent position that Darwin and Wallace created for it — as a mechanism for adaptive evolution. One of the most important subsidiary conclusions of genetical research in the last half-century is the recognition that developmental plasticity or individual adaptability to environmental heterogeneity is an evolved character under genetic control. C.H. Waddington⁸ pointed out as long ago as 1942 that genetic modifications to adaptable systems can stimulate the inheritance of acquired characters. In relegating discussion of this fundamentally important concept to a dismissive footnote, Steele does both himself and modern genetics a disservice. It is the current fashion to level popular attacks at the theory of evolution. Twice in the past year Darwin could be found staring gloomily from one corner of the *Sunday Times Magazine*, whilst first Lamark and then Professor Stephen Gould of Harvard University confronted him from the opposite corner. Whether Professor Gould would wish to represent the opposition to classical Darwinism seems doubtful, but the earlier confrontation with Lamark was designed to represent the challenge raised by Steele's work. If Steele is feeling the heat of an intensive critical scrutiny, both of his ideas and of his experiments, it is because, like Icarus, he has flown close to the Sun. □

Small is beautiful — portrait of a mitochondrial genome

from Piet Borst and Leslie A. Grivell

PUBLICATION of the complete sequence of the 16,569-base pair human mitochondrial DNA (mtDNA) on p.457 of this issue of *Nature* is a landmark in biology. It comes only 15 years after mtDNA from vertebrates was found to consist of rather small DNA circles¹⁻³, and only 6 years after Sanger and his co-workers developed the sequencing methodology to tackle such large molecules. Together with the virtuoso analysis of mitochondrial transcripts by Attardi's group, reported on pages 465 and 470 of this issue of *Nature*, the sequence provides not only a wealth of information on mitochondrial biogenesis, but also insights into the genetic code and decoding, and into what it takes to make a ribosome, to read messenger RNA (mRNA) and on the minimal requirements for transfer RNA (tRNA) function.

The organization of information in human mtDNA shows an economy never before encountered in nature. Not only does the sequence pack the genes for 2 ribosomal RNAs (rRNAs), 22 tRNAs and 13 assorted proteins so tightly that there are few or no non-coding bases between them, but some of them have been stripped of features that have come to be regarded as *de rigueur* for a respectable gene. In particular, the mRNAs lack non-translated

leader and trailing regions. Furthermore, over half of them do not even have a complete stop codon; this only materializes on polyadenylation of the 3' terminus, whereby the terminal U or UA of the gene is converted to the stop codon UAA. Even the transcription-translation machinery used for the expression of human mitochondrial genes has not escaped the drive for economy; features familiar in the genomes of all organisms from viruses to man have been thrown overboard. Thus, transcriptional regulation is a primitive affair, with only one promoter for RNA synthesis on each strand. Consequently, the genome is completely and symmetrically transcribed. Differential gene expression is apparently achieved by a combination of transcription-attenuation, control of the cleavages required to generate transcripts of individual genes and stability of the final transcripts. The rRNAs have been reduced to a size (1,559 and 954 nucleotides) not found outside mitochondria; a 5S rRNA is absent and only 22 tRNAs, of highly unorthodox structure, are used to read all codons. This remarkable feat is accomplished by having some tRNAs read four codons and in these, U is in the first position of the anticodon, permitting U:N wobble.

An important spin-off of the sequence analysis is the finding that the genetic code in human mitochondria differs from that used in other genetic systems: UGA is read as tryptophan rather than 'stop', AGA and AGG as 'stop' rather than arginine, AUA as methionine rather than isoleucine, and AUA or AUU is sometimes used as an initiation codon instead of AUG. The genetic code is therefore not universal.

For the mitochondriacs who spend their days studying mitochondrial biogenesis, the human mtDNA sequence also has an interesting bonus. In addition to the genes for subunits of major membrane proteins like the cytochrome *c* oxidase, apocytochrome *b* and the ATPase complex, which were already known to reside in mtDNA, sequence analysis has unearthed eight URFs (unassigned reading frames, coding for as yet unidentified proteins). There is very little doubt that these sequences represent protein genes because they are conserved in the bovine mtDNA and, moreover, it is highly improbable that such a tightly packed genome would contain non-functional genes. The function of the

Piet Borst and Leslie A. Grivell are in the Section for Medical Enzymology and Molecular Biology of the Laboratory of Biochemistry, University of Amsterdam, The Netherlands.

Fig. 1 Organization of yeast and human mitochondrial genomes. The figure summarizes our present knowledge about the organization of genes on human mtDNA and the yeast *Saccharomyces cerevisiae* strain KL14-4A (~78,000 base pairs). For clarity and to accommodate both genomes within the same format, the human genome has been drawn approximately 2 times 'larger-than-life' relative to yeast. On both DNAs, sequences encoding known gene products are shown as black bars, URFs are indicated by stippled areas and open circles represent a tRNA gene. Transcription is in a clockwise direction, unless otherwise indicated. The cross-hatched region in the yeast genome shows the location of the *var1* genetic determinant, which is involved in the specification of a mito-ribosomal-associated protein. The exact localizations of the DNA sequences encoding this protein are as yet unknown. For yeast, the figure is based on DNA sequence data from several laboratories¹⁸⁻²³, supplemented with unpublished data from our own laboratory (L.A.M. Hensgens, personal communication). Sequenced areas are denoted by a continuous line, unsequenced areas by a broken line. The inventory of genes is thus a provisional one. In the split genes for apocytochrome *b* and COI introns not containing an URF are shown as open bars; exon nomenclature is from refs 19 and 23. The URF in the intron between B2 and B3 in the cytochrome *b* gene has been identified as the C-terminal half of an RNA processing enzyme or maturase (see refs 19 and 24). COI, II, III are subunits of cytochrome *c* oxidase, *cyt. b* is apocytochrome *b*, ATPase 6 and 9 are subunits 6 and 9 of the ATPase complex. URFs are unassigned reading frames. The arrows indicate genes transcribed from the strand opposite the one that encodes most genes.

Fig. 2 Comparison of the gene and mRNA for apocytochrome *b* in yeast (see ref.24) and man (refs 4, 5 and S. Anderson *et al.* p.457 of this issue of *Nature*). Coding sequences are shown as filled-in bars and introns as open bars.

proteins corresponding to the URFs remains a matter of speculation (RNA processing? Ribosomal proteins?).

How representative of mitochondrial genetic systems is the human's? The size of mtDNAs from sea urchins, flatworms, insects and man is similar⁴ and the relative positions of tRNAs and other transcripts on human and toad mtDNA is virtually the same⁵. But an entirely different situation is found in yeast, which contains a fivefold larger mtDNA. Figure 1 compares the overall gene order in the two mtDNAs. Yeast contains a series of URFs showing no significant homology with their human counterparts, but has a set of genes for major membrane proteins which are about 50 per cent homologous to their human mitochondrial equivalents. The order and the space in which these genes are arranged in the DNA are, however, completely different. The striking difference in compactness is exemplified by the comparison of the apocytochrome *b* genes, presented in Fig. 2. The coding sequences are almost identical in size, but the yeast mRNA has a leader sequence of 1,000 nucleotides, whereas the human mRNA has none. The yeast gene is split by five introns, the human gene (like all other human mitochondrial genes) is not. The yeast gene has a non-translated 3'-trailing region of about 50 nucleotides; the human gene has no such region and even lacks a complete stop codon. The human mRNA is polyadenylated; the yeast mRNA seems not to be. Obviously there is no pressure for maximal economy on yeast mtDNA. Further evidence of that comes from the long non-coding stretches between genes.

Although RNA processing is prominent in both human and yeast mitochondria, in yeast transcription appears to start from at least five separate promoters⁶ and tRNA punctuation, so elegantly used by human mitochondria in RNA processing (see p.470-475 of this issue), does not have a role. With less pressure for economy one would expect the yeast rRNAs and tRNAs to be less 'petite' and unusual than their human counterparts. This is the case; the rRNAs in yeast mitochondria are about 3,200 (ref.7) and 1,660 (ref.9) nucleotides long and the tRNAs, although lacking some of the common features of tRNAs used in

non-mitochondrial genetic systems⁸⁻¹¹, are less bizarre than the human ones. As in the human, the yeast mitochondria have some tRNAs able to read four codons but they contain more iso-accepting tRNAs, the total gene number now being at least 25, against 22 in human mtDNA. Finally, yeast, like human, mitochondria read the UGA codon as tryptophan rather than 'stop', but they do not share with human mitochondria the unusual assignments of the AUA, AGA and AGG codons. Instead they read the CTN codon as leucine rather than threonine¹², so there is not even a common code in different mitochondria.

Why does human and animal mtDNA look like a 1981 university department, with everything reduced to minimal size without anyone actually being fired, whereas an equivalent set of genes is spread luxuriously over 78,000 base pairs in yeast? We think that the key to an understanding of these differences lies in the rapid evolution of the mtDNA genes that code for rRNAs and tRNAs. For instance, the large rRNA from mouse¹³ and rat (C. Saccone, personal communication) mitochondria share only 68 per cent homology. (Compare this with the 74 per cent homology between the 16S rRNAs of *Zea mays* chloroplasts and *Escherichia coli*¹⁴.) And, at most, human and beef tRNA^{thr} are only 74 per cent homologous. Furthermore, the T ψ C loop, which has a constant seven-base length outside mitochondria, is three bases long in human and eight in bovine tRNA^{thr} (ref.15).

In our opinion this high evolutionary divergence of rRNA and tRNA genes in the mitochondria of closely related species is most easily explained by the low demands made on the mitochondrial translation system. This system has only to produce a very limited number of proteins and usually at a constant relative rate. It may therefore evolve more rapidly than a system which has to produce a large number of proteins at maximal efficiency and subject to various translational controls. Different selective pressures must have pushed animal mtDNA into extreme economy but yeast into maximizing the A+T content. The nature of these pressures is unknown.

If the mitochondrial genetic system can

take more change than other systems, it is possible that further searches in the backstreets of biology may uncover additional surprises. The small mitochondrial genomes of, for example, *Chlamydomonas*, with 15,000 base pairs¹⁶, or *Trypanosoma brucei*, with 20,000 base pairs¹⁷, exhibit different or more extreme solutions to the pressure for economy than human mitochondria. Indeed, the trypanosomes appear to have even smaller rRNAs in their mitochondria (1,230 and 640 nucleotides) than man¹⁷. The study of such extremes may deepen our insight into the minimal requirements for a functional genetic system and provide clues about the evolutionary pathways that might have been followed to develop the more sophisticated mechanisms of gene expression used by present-day bacteria and eukaryotes. □

Thrombosis: a molecular approach to therapy

from P.J. Gaffney

VENOUS THROMBOSIS is thought to be initiated by the thrombin-mediated conversion of circulating fibrinogen to fibrin and the deposition of long fibrin polymers on the vessel wall, with the simultaneous aggregation of platelets and entrapment of other cellular components of blood. There is evidence that fibrin deposition is also involved in the progressive growth of atheromatous lesions, which characterize coronary artery disease. While present-day pharmacological approaches to the alleviation of occlusive vascular disease frequently fail to solubilize the target fibrin without hazardous systemic effects, in this issue of *Nature* (p.505) Smith and his colleagues describe a novel chemical tactic using chemically modified enzymes and activators, which allows the delivery of a fibrinolytic action direct to the target fibrin, leaving the circulating components of the haemostatic system unaffected. Current views about the molecular reactions involved in fibrin formation and destruction allow a better appreciation of the ingenuity of this new approach to thrombolytic therapy.

The generation of thrombin is a central event in the initiation of a thrombus in that this enzyme (1) causes platelets to aggregate, (2) activates fibrinogen to fibrin, and (3) converts an inactive plasma transglutaminase (Factor XIII) to its active form. The latter two reactions are involved in the establishment of an organized insoluble fibrin network which 'cements' the various components of a thrombus together. The interaction of thrombin with fibrinogen involves the removal of small peptides from the dimeric fibrinogen molecule¹, exposing a previously masked dimeric polymerization site on the fibrin monomer² which can attract two fibrinogen molecules in a polymerizing reaction. These latter fibrinogen molecules are converted to fibrin by the action of thrombin, and further accumulation of fibrinogen feeds the multi-branched growth of the fibrin polymer network. Activated Factor XIII catalyses the formation of stable glutamyl-lysyl cross-links³ between the chains of the soluble forming fibrin and this cross-linking process is completed in the insoluble fibrin found in most established thrombi⁴. Thus the *in vivo* formation of fibrin clots is a dynamic process with all the events in a series of reactions being interdependent.

Of necessity there are a number of control mechanisms on clot formation. While inhibitors of thrombin (particularly ATIII) are crucial in the control of thrombin generation, it is generally agreed that the fibrinolytic system protects against fibrin deposition and thus against most

forms of thrombosis. The fibrinolytic system consists of a circulating proenzyme (plasminogen) and a plasma activator (plasminogen activator), the latter being stored in and released on demand from the endothelial cells lining the vessel wall. The interaction of plasminogen activator with plasminogen produces the active serine protease, plasmin, which is very rapidly neutralized by natural inhibitors in the plasma, notably α_2 -antiplasmin⁵. The role of the fibrinolytic system in controlling fibrin generation is best exemplified during disseminated intravascular coagulation, which is a serious complication in a variety of seemingly unrelated conditions (such as cancer, pregnancy and septicaemia). During this form of intravascular coagulation the systemic generation of thrombin is accompanied by the activation of the fibrinolytic system which digests the forming fibrin before it can act as a focus of local thrombus formation on the vessel wall. It seems that as fibrin forms, it orchestrates its own destruction; some of the mechanisms of this orchestration process are now understood (for review see ref.6).

Plasminogen activator and plasminogen bind strongly to forming fibrin while the major fibrinolytic inhibitor, α_2 -antiplasmin, has no such affinity. Thus, this inhibitor, which has such a powerful and immediate neutralizing effect on free plasmin, can only mildly affect plasmin attached to forming fibrin. The preferential binding of plasminogen to fibrin is via a lysine-binding site on the A chain of the plasminogen molecule, which is distinct from that region of the molecule where the catalytic site resides. This lysine-binding site and the active site of plasmin both combine with α_2 -antiplasmin during the rapid neutralization of plasmin. Thus, the protective effect of fibrinolysis against thrombosis seems to be regulated by the localization of plasminogen activator-plasminogen complex on, and the exclusion of inhibitors from, the surface of the forming fibrin⁷.

It is reasonable to propose that the mechanisms described above for systemic intravascular coagulation also apply during the localized coagulation which precedes the occurrence of thrombosis. Should the fibrinolytic system be unable to control such coagulation episodes, it probably cannot digest the consequent organized thrombi containing resistant cross-linked fibrin. There is, indeed, a developing consensus that enzymes from entrapped cells are responsible for the

spontaneous lysis of thrombi⁸. This non-plasmin form of fibrinolysis probably proceeds quite slowly, whereas urgent and effective thrombolytic therapy is required during life-threatening thrombosis, which involves imminent tissue death in vital organs.

The major aim of treatment must be the destruction of the target fibrin in the thrombus, while leaving unaffected the fluid components of the blood. Though two potent fibrinolytic agents, streptokinase (SK) and urokinase (UK), have been in clinical use for the past 20 years, wholly satisfactory therapy has not yet been developed. Urokinase directly converts plasminogen to plasmin while SK forms an equimolar complex with plasminogen or plasmin (SK-plasminogen or SK-plasmin) and this complex, like UK, converts plasminogen to plasmin⁹. While the systemic plasmin so formed is rapidly neutralized by α_2 -antiplasmin, any plasmin generated in excess of the neutralizing effect of α_2 -antiplasmin arguably attacks not only the occlusive thrombus, but also circulating fibrinogen and other components of the haemostatic process. Since these effects are systemic and the thrombus may be localized at one point in the circulation, it is not surprising that both the destruction of fibrinogen and the consumption of α_2 -antiplasmin occur. Damaged circulating fibrinogen and its effect on platelet aggregation have been proposed as major causes of the haemorrhages sometimes occurring during infusion of SK and UK for the relief of occlusive vascular disease¹⁰.

Smith and his colleagues, in their novel approach to the therapy of venous thrombosis, exploited the differential affinities of plasmin for fibrin and α_2 -antiplasmin and demonstrated that acylation of the active site serine allowed plasmin to bind exclusively to fibrin without being inhibited by α_2 -antiplasmin. Likewise, an equimolar SK-plasmin activator complex was acylated and, when infused systemically in experimental animal models, it bound to thrombi without activating the circulating plasminogen. The authors demonstrated the *in vitro* deacylation of plasmin and activator while bound to fibrin and their results in animals indicated a similar deacylation process on the surface of experimental thrombi, causing effective lysis. During these experiments little or no systemic side effects were observed.

This approach provides an attractive alternative to the somewhat hazardous systemic approaches used to date in thrombolytic practice, which are quite often accompanied by the destruction of some essential haemostatic components of

P.J. Gaffney is at the National Institute for Biological Standards and Control, London.

blood with accompanying danger of haemorrhage. The successful targeting of the fibrinolytic action to the fibrin in experimentally induced clots in rabbits and dogs, without overt systemic effects, opens up a new approach to thrombolytic therapy. However, before undue optimism is generated, there is a need to demonstrate these different thrombolytic and systemic effects using acylated enzymes and activators in a whole human system (that is, in a system where a human thrombus is perfused with human blood). The efficacy of this new approach must also be tested in other models of thrombosis which are more

closely associated with the vessel wall. Should these approaches be successful, then a new dimension in the treatment of thrombotic disease may soon be available for testing in clinical trials. □

Stable clocks and the theory of relativity

from G.J. Edwards

EINSTEIN'S theory of relativity is to my mind the most elegant of all scientific theories. Based on the simple hypothesis that all local, freely falling, non-rotating laboratories are fully equivalent for the performance of all physical experiments (the principle of equivalence), the theory has vast ramifications which extend throughout physics and form a basis for our understanding of the structure of the Universe. The theory has, of course, been something of a theoretician's paradise and an experimentalist's hell, but the past twenty years have seen two developments which somewhat redress this imbalance. These are the ability to hurl sensitive equipment into space and the great improvements of oscillators (clocks) such as masers, lasers and atomic clocks, some of which now have stabilities of 1 part in 10^{14} or so over significant periods of time. The kind of accuracy possible using these aids is exemplified by a recent experiment by Vessot and colleagues (*Phys. Rev. Lett.* **45**, 26, 2081; 1980) which is the most precise confirmation to date of the change in the rate of a clock moving in a gravitational field. The experiment also points the way for future projects which will probe accurately the actual structure of space and time.

In the above experiment (carried out by the Smithsonian Astrophysical Observatory and the George C. Marshall Space Flight Center, US) a very stable clock was launched by rocket to a height of 10,000 km in a near-vertical trajectory. The clock was a hydrogen maser operating at 1,400 MHz and with a stability of 1 in 10^{14} over 100 seconds. After the 18-g launch acceleration, the spacecraft containing the maser went into free fall, allowing about 100 minutes of experimental time, during which the frequency shift in the maser

Fig. 1: Simplified schematic diagram of the experiment by Vessot *et al.*

signal radiated to Earth was measured and, after correction, compared with the value predicted by relativity theory (Fig. 1). The main correction was in fact large, being caused by the non-relativistic Doppler shift in radiation from a moving source. Its magnitude was obtained using a separate two-way transponder system between Earth and the spacecraft, as the returning signal contains essentially only the Doppler shift. Finally, the position and velocity of the spacecraft need to be known accurately, and these parameters were deduced from the Doppler-shifted signals received at five tracking stations.

The residual fractional shift, $\Delta f/f_0$, in the maser signal is, according to the theory of relativity, given to first order by:

$$\frac{\Delta f}{f_0} = \frac{1}{c^2} [\phi_s - \phi_e - \frac{1}{2} |V_e - V_s|^2 - r \cdot a]$$

The first term is the gravitational redshift (ϕ_e and ϕ_s are the Newtonian gravitational potentials on Earth and at the maser), while the second term involves the relative Earth-spacecraft velocity and is the famous time-dilation effect for a moving

Fig. 2: Frequency residuals and predicted effect during mission.

clock of special relativity. The last term is a residual Doppler shift due to Earth acceleration.

The result of this difficult experiment is indicated in Fig. 2. Clearly the experiment was a great success and the authors quote the overall uncertainty as given by:-

$$\frac{\Delta f}{f_0} (\text{experiment}) = \frac{\Delta f}{f_0} (\text{theory}) [1 + (2.5 \pm 70) \cdot 10^{-6}]$$

The previous best direct verification of the velocity-dependent term is from a measurement of the lifetime of fast-moving muons by Bailey *et al.* (*Nature* **218**, 301; 1977) with an accuracy of 1 in 10^3 . The gravitational shift had previously been confirmed at the 1 per cent level by Pound *et al.* (*Phys. Rev.* **140**, 3B, B788; 1965) using the Mossbauer effect.

Clearly the new result is a significant boost for the theory of relativity and the same is true of other, recent experiments using very stable oscillators. In one of these, Brillet and Hall (*Phys. Rev. Lett.* **42**, 9, 549; 1979) rotated a helium-neon laser working at a wavelength of $3.39 \mu\text{m}$ and locked to a cavity, to check for small anisotropies in space, due for instance to the Earth's motion with respect to the Sun or the cosmic background radiation. They could find no anisotropy at the 1 in 10^{15} level, a 4,000-fold improvement over the best previous attempt. Another experiment by Hafele and Keating (*Science* **177**, 166; 1972) involved flying four very stable caesium clocks around the world in aeroplanes. This experiment is conceptually identical to that of Vessot *et al.*, but less precise. Again, theory and experiment were in agreement.

The experiments outlined above are important indications of the results which will almost certainly be obtained by the use of very stable clocks within the next few years. Besides the general theory of relativity, there are a number of other theories of gravitation which predict different values for the space-time 'curvature' in gravitational fields. The theories differ in their predictions by very small terms which are second order compared with the components of the equation above. Some of these terms have already been measured to modest accuracy, for example by observations on the advance in

the perihelion of the orbit of Mercury and the bending of light rays round the Sun. (For a general review of relativistic, gravitational experiments see Rudenko *Sov. Phys. Usp.* **21**, 11, 893; 1978). However, tests using stable clocks should be able to advance significantly our knowledge in this area.

One such ambitious venture is the solar probe (European Space Agency) which will fly, amongst other things, clocks very close to the Sun, where the gravitational field is very much greater than on Earth. Besides obtaining valuable information on the Sun's structure, the experiment should enable us to distinguish accurately between several of the competing theories. Another experiment proposed by Will (*Metrologia*

13, 95; 1977) is the comparison of two different types of very stable clocks on Earth. Certain (metric) theories of gravitation predict that all clocks, irrespective of their construction, have identical gravitational redshifts while another class of (non-metric) theories predicts small shifts between different types of clock. Such an experiment would require clock stabilities in excess of 1 part in 10^{15} .

All of these tests impose extremely strict requirements on the stability of clocks and great care in the design of the experiments. The reward might be that we discover tiny but significant effects which would imply a change in our idea of gravity as significant as the difference between the Newtonian and Einsteinian theories. □

this process operating in close binary star systems in our galaxy. But at the centre of quasars things are likely to be less simple, the infall of material will probably be more chaotic for example. Before the radiation generated deep down at the centres of quasars is detected by our instruments it will have interacted, that is been scattering absorbed and re-emitted, by material within the quasar. These effects modify the observed continuum spectrum so a simple power law fit that might arise from synchrotron radiation does not usually provide good agreement with the observations. The multifrequency observations now possible using satellites and ground based telescopes have proved very useful, and the various lumps and bumps by which their spectra deviate from a smooth distribution are now the subject of much research.

Another problem which has attracted much interest since the launch of the Einstein X-ray satellite, is the contribution made by quasars to the X-ray background. The first X-ray results lead to the embarrassing conclusion that if the X-ray emission from all such objects were summed out to large distances it would more than account for the observed diffuse X-ray background in the range 1–3 keV. Of the many assumptions which went into this calculation at least one now appears to have been unjustified. The original sample was biased towards radio loud quasars and the contribution of all quasars was based on the assumption that the majority, which are radio quiet, had similar X-ray luminosities. A larger sample of X-ray quasars shows that this is not so. Radio loud quasars tend to be stronger X-ray sources than the radio silent majority. We now believe that quasars contribute somewhere around 40 per cent of soft X-ray background.

A consensus seems to have been reached on a basic model of the line spectra of quasars, both emission and absorption, although it should be borne in mind that the following numbers are order of magnitude at best. In a typical quasar the emission lines arise in a region about 1 parsec in diameter and this volume contains about 100 solar masses of ionized gas. The distribution of the gas is far from uniform and consists of a large number of dense clouds (perhaps 10^{12} of density 10^9 particles per c.c.). These clouds may not be fully ionized and could contain an unknown amount of neutral gas. The cloud model provides a simple approximation and no information is available on the shapes and distribution around the nucleus. It seems that the dominant source of ionization is from the central source and not from collisions between the clouds, although this process is known to produce the emission lines in some nearby active galaxies. One important and recently recognized feature of the ionization

Quasars: what and where?

from Martin Ward

RECENTLY the Royal Astronomical Society was host to a discussion meeting* on Quasars which, although short, did provide an insight into the astronomical communities' current views on the nature of quasars. The talks appeared to divide naturally into two categories — concerning what quasars are and concerning where they are.

The latter question relies heavily on statistical arguments, often a weak point amongst astronomers. A study of pairs of quasars with very similar redshifts shows that, assuming the redshift is a result of the expansion of the Universe, their projected separations in space are between 5 and 30 million parsecs. As clusters of galaxies are thought to be components of 'superclusters' with dimensions of comparable range the observations may suggest that quasars are in superclusters too faint to be seen.

A minority view is that the origin of the high redshifts, at least in some cases, is not due to the Hubble flow, and hence cannot be used in the standard way to determine the distance of the quasar. Rather, it is claimed that some component of the redshift is an intrinsic property of the quasar itself. Supporting evidence comes from the incidence of high redshift quasars near to low redshift bright galaxies — an unlikely state of affairs, advocates of the non-cosmological redshift would say, unless the quasars and bright galaxies are in some way related, by ejection of the quasars from the bright galaxies for example. A related problem is of quasar alignments (see *News and Views*, **289**; 533, 1981). An impressive number of pairs, and some multiple quasars have been found near to galaxies. The crucial question is whether these distributions are projection

effects, and hence occur by chance, or imply a genuine physical association. The majority of astronomers still doubt a physical association hypothesis because of the *a posteriori* statistics used, and also because no accepted theoretical framework exists to explain the large intrinsic redshifts. In order to calculate accurately the chances of finding a quasar near to a bright galaxy by projection effects, one needs to know the surface density of quasars. This number is very uncertain at faint magnitudes and different assumed densities will change radically the likelihood of a chance quasar/galaxy pair. So the question remains open, but it is unlikely that the majority view will change without evidence of physical association — as might be provided by an unambiguous detection of connecting material for example. Talks given during the rest of the meeting, addressed the question of what quasars are, and it was assumed without comment that quasars are distant and that redshift is a distance indicator.

The continuum radiation from a large number of quasars has now been observed from X-ray to radio frequencies. Variations in the intensity of this radiation over short timescales, in many cases days, strongly suggests an origin in the very central regions of the object. If quasars are assumed to be at great distances it is difficult to see what sort of powerhouse is capable of generating these enormous energies. A general picture which has gained acceptance over the last few years requires the presence, at the center of quasars and related objects, of a super-massive object (black hole) equivalent to something like 10^8 to 10^{10} solar masses. Material, possibly debris from stars torn apart by tidal forces, then falls onto the central object releasing energy as it does so. There is good evidence for a similar, although very much scaled down, version of

*The meeting was held in London on 13th February 1981 and was organised by M. G. Smith and R. F. Carswell.

Martin Ward is in the Institute of Astronomy, University of Cambridge.

process is the role played by soft X-rays which penetrate deep into the gas clouds. By considering this effect there is better agreement between the observed and the theoretically predicted emission line ratios. There is disagreement over whether obscuration by dust is important. This effect reduces the intensity of short wavelength emission lines relative to longer wavelength ones. It is certainly true in galaxies that where there's gas there's dust, but the relative amounts in quasar emission line clouds is at present unknown.

Finally the absorption line problem. It has been known for some time that the broad emission line Lyman alpha often has, superimposed on its profile, numerous narrow absorption lines which are usually blue-shifted with respect to the quasar. This is the so-called Lyman alpha 'forest'. The

question is, do these absorptions arise in material near to the quasar or elsewhere along the long line of sight between us and it? Opinion now favours the latter interpretation. An explanation in which the absorption occurs in the halos of galaxies is an interesting possibility. If this is correct we could use the light from background quasars to study the properties and statistics of galaxies far too distant to be detected by their own feeble light.

It would be wrong to give the impression that a revolution has taken place in our knowledge of what quasars are over the last few years, but neither is pessimism justified. The new multi-frequency continua and high resolution spectral line observations, together with variation studies have improved our understanding. Progress is being made. □

Triggering of volcanic eruptions by Earth tides

from R.S.J. Sparks

A recent study of Kilauea and Mauna Loa volcanoes in Hawaii (D. Dzurisin *Geophysical Research Letters* 7, 925; 1980) shows a weak but significant correlation of the Earth tide maxima with eruptions of Kilauea. No correlation at all was seen with the activity of Mauna Loa — a result which serves to emphasize how individual the behaviour pattern of very similar volcanoes can be.

The stress changes induced in the Earth's crust by fortnightly Earth tides are very small (maximum of 10^{-2} bar) compared with the levels of tectonic stress ($10^1 - 10^3$ bar) and the probable stresses required to fracture a volcanic edifice and trigger eruptions. Although many studies have attempted to link earthquakes with tidal stressing, the results have generally proved negative or inconclusive. One exception was a study of after-shocks by Ryall and others (*Bull. seism. Soc. Am.* 58, 215; 1968) where a good correlation with fortnightly Earth tides was demonstrated.

In a volcanic eruption, pressure builds up over periods of hours to months due to the ascent of lava into the volcano, the exsolution of volatiles or the entrapment of ground water. When the pressure on the volcanic edifice exceeds the strength of the rock, fracturing occurs and allows lava and gas to reach the surface. Fracture strengths of rock in tensile failure are probably in the range 10 to 100 bar, again very much larger than tidal stresses. Thus, at first sight, a correlation with Earth tides

seems unlikely given many other factors which will control the formation of suitable fractures.

Mauk and Johnston (*J. geophys. Res.* 78, 3356; 1973), however, have pointed out that it is the rate of stress accumulation that can be important. Fortnightly Earth tides can have stress accumulation rates of up to 10^{-5} bar s^{-1} . In volcanoes such as Kilauea the stress accumulation rates by increase in fluid pressure within the magma reservoir are as low as 2×10^{-7} bar s^{-1} . Thus, if stress is slowly building up Earth tides could trigger the eruption. On the other hand, stress accumulations of 5×10^{-5} to 8×10^{-4} bar s^{-1} , greatly exceeding the tidal rates, have been recorded from volcanoes in New Zealand.

The study by Dzurisin examines the two volcanoes, Kilauea and Mauna Loa, for which more data are available than any other volcano. The correlation between Earth tides and Kilauean eruptions is reasonably convincing — the probability of an eruption during a week centred on tidal maximum is nearly twice as much as the probability of an eruption in a week centred on tidal minimum. For Mauna Loa, however, there is no correlation. An important lesson is that it is often very dangerous to transfer the results from one volcano to another. Volcanologists should not use Earth tides in general predictions until they know the behaviour of their particular volcano very well. Most of the world's dangerous volcanoes, such as Mount St Helens, simply do not have a long enough record to find out whether there is a correlation. □

100 years ago

THE ST. PETERSBURG DYNAMITE MINE

The following account of the bomb recently discovered in St. Petersburg, extracted from Russian sources, gives a remarkable picture of the state of society in the empire, where able chemists and expert miners can be found to engage in such desperate undertakings.

It appears from a sketch-plan which accompanied the translation put into our hand, that the mine extended from one side of Malaya Sadobaya Street to the centre of the roadway; the total length of the mine gallery being fifteen paces, the street must be thirty paces, say seventy-five feet wide.

The gallery terminated in a chamber about double its diameter, and in this was found the charge contained in a case twenty-two inches long and eight inches diameter, weighing sixty-five pounds, and beside this a glass jar contained about thirty pounds more of the explosive substance, apparently an excess quantity over that required for the actual explosion. The explosive consisted of a species of dynamite made by mixing nitro-glycerine with powdered charcoal. The description of the fuse, as contained in the Russian account, is very obscure, but would appear to have consisted of a wide heavy glass tube containing an explosive, described some time back in *Nature*, and prepared by mixing nitro-glycerine with about 10 per cent. of gun-cotton, the result being a very explosive substance of a partially gelatinous character. In the midst of this, and surrounded by a mixture of potassic chlorate and antimonious sulphide, was a sealed glass tube containing concentrated sulphuric acid and a leaden weight. The whole was then apparently connected with the dynamite in the case by means of an india-rubber tube also containing explosives. If this was the actual construction the *modus operandi* of the conspirators was very simple, for the heavy glass tube had only to be allowed to fall, when the lead would have broken the sulphuric acid tube, and the chlorate mixture would have at once inflamed, and the explosion of the jelly would have communicated by means of the rubber tube with the torpedo. At the same time it is very difficult to imagine the reasons which could have induced the conspirators to adopt so crude a method when, as it appears from the account, they had at their disposal in the room adjoining that from which the mine was driven no less than four galvanic batteries, with which the explosion could have easily been instantaneously effected by those on the watch for the passage of the intended victims, a method of operation much more consonant with the skilled character of the other parts of the work.

Whatever may have been the real mode intended to have been used by the conspirators, the results would have been sufficiently frightful, as it is probable that the charge found would have made a 'crater' of about fifty feet in diameter.

Some of our readers may be glad to learn that the French Association has resolved to curtail the number of scientific meetings in order to extend the time left for excursions and festivals. The programme includes two receptions by the Mayor of Algiers, one by the Governor-General, and a large Arabian *fête* called *Bitu*, dancing and singing by native women, &c. Possibly the reported massacre of the Flatters Expedition may put a stop to these ultra-scientific festivities.

From *Nature* 23, 7 April, 531, 542, 1881.

Erratum

In *Monitoring Mount St Helens* from M. McCormick (*News and Views* March 12, 290, 88, 1981) the value of aerosol mass added to the background stratosphere calculated from lidar data was incorrectly printed as being 0.4 to 0.6×10^{10} metric tons. The value should have been 0.4 to 0.6×10^6 metric tons (p.88, line 46) which agrees with that calculated from SAGE data. The predicted warming of the stratosphere near the peak aerosol concentration at 18km (p.88, line 62) was also incorrectly printed as 'a degree' instead of 'tenths of a degree'.

REVIEW ARTICLE

Membrane protein oligomeric structure and transport function

M. Klingenberg

Institut für Physikalische Biochemie der Universität München, Goethestrasse 33, 8000 München 2, FRG

Proteins which traverse membranes tend to have a dimeric structure in which the dimer is arranged asymmetrically across the membrane with the axis of symmetry perpendicular to the membrane plane. This general structure is well suited to the function of transporting nutrients across the cell membrane.

THERE is growing evidence that membrane proteins exist in oligomeric (usually dimeric) form, based on studies both of the intact membrane and of solubilized proteins. In reviewing the evidence here, I shall consider only those proteins which clearly or probably traverse the cell membrane. It is my aim to show that the structural features of these proteins have functional consequences which are compatible with the experimentally established prerequisites for carrier systems.

Examples of oligomeric membrane proteins

Studies of the intact membrane, for example with cross-linking reagents^{1,2}, suggest that some membrane proteins occur in oligomeric form but more compelling evidence has come from studies of the solubilized membrane proteins. Only in the past decade, by more judicious handling of nonionic detergents, has the isolation of membrane proteins reached a stage at which the purified proteins can confidently be considered undenatured and intact. This has allowed the oligomeric states of some solubilized membrane proteins to be demonstrated by direct measurements of molecular weight. Based on data from such studies I suggest that oligomericity can be used as a criterion to determine whether a membrane protein isolated in these detergents is intact, because cleavage of oligomers by detergents often leads to denaturation.

A survey of some selected membrane proteins with oligomeric structure is given in Table 1. Although much evidence has been derived from chemical cross-linking procedures, these are not free from artefacts. Less equivocal data can be obtained with the isolated protein, by determination of the molecular weight (by ultracentrifugation) and of the number of active sites per protein. Any complication due to artificial aggregation of hydrophobic proteins can be largely excluded by the appropriate use of nonionic detergents. If the functional molecular weight calculated from the number of sites per protein agrees with that determined by hydrodynamic methods, there can be little doubt that the isolated protein is in the native oligomeric state.

In the intact membrane, cross-linking experiments for detecting oligomeric proteins have rarely been successful³. Nevertheless, erythrocyte band 3 protein (identified with the anion carrier⁴) has been shown to occur as a dimer⁵ and to span the membrane⁶. Also, $(\text{Na}^+ + \text{K}^+)\text{ATPase}$ has been cross-linked⁷ in the membrane to form a dimer of the large α and β subunits, which indicates that this pump may exist as a dimer $(\alpha\beta)_2$. The ADP/ATP carrier in mitochondrial membranes can be shown by combined cross-linking and immunochemical methods to be a dimer (M. L. Vitali and H. P. Schultheiss, unpublished data). For Ca^{2+} -ATPase there is some evidence of an oligomeric state in the membrane but it is equivocal⁸.

More abundant and clear-cut evidence for oligomeric structure is provided by the isolated membrane proteins. If solubilized with nonionic detergents, these proteins form micelles with an increased particle size due to the bound detergent. The detergent obscures the true hydrodynamic properties of the

proteins but this can be allowed for by use of appropriate corrections⁹. The membrane protein preparations in the nonionic detergents are mostly monodisperse and, according to several criteria, are undenatured, retaining their native structure. Using Triton X-100 my colleagues and I have isolated seven different membrane proteins from mitochondria¹⁰⁻¹³, chloroplasts¹⁴ and bacteria^{15,16} and have determined their molecular weights by ultracentrifugation¹⁷⁻¹⁹.

The band 3 protein of erythrocytes isolated with Triton X-100 is a dimer—this agrees with *in situ* cross-linking studies⁵. However, if solubilized by acetic acid, a dynamic monomer-oligomer equilibrium is observed²⁰. This preparation may not be native according to the criteria described above. Among the mitochondrial proteins isolated with Triton X-100, the ADP/ATP carrier was first recognized as a dimer with two identical subunits^{17,21}. Extending these methods, other mitochondrial proteins such as cytochrome *b* (ref. 10) and the cytochrome *bc*₁ complex^{13,18} were purified in defined oligomeric states. The highly hydrophobic cytochrome *b* was characterized as a dimer¹⁰ and the cytochrome *bc*₁ complex, consisting of several different subunits, was found to be a dimer with each subunit present at least twice^{18,22}. Other dimers isolated in Triton include the cytochrome *c* oxidase complex²³, the uncoupling protein from brown fat mitochondria¹⁹, the acetylcholine receptor from postsynaptic membranes and the triose phosphate- P_i exchange carrier of chloroplasts¹⁴. Two membrane-bound dehydrogenases from bacteria, formate dehydrogenase¹⁵ and fumarate reductase¹⁶, which also form dimers, are not listed in Table 1 because they do not penetrate the cell membrane and bind only a relatively small amount of Triton.

When isolated with the nonionic detergent Lubrol, $(\text{Na}^+ + \text{K}^+)\text{ATPase}$ is a dimer by ultracentrifugal studies^{24,25}; in the same detergent Ca^{2+} -ATPase is a tetramer⁸ but this may result from nonspecific aggregation as the tetramer can be dissociated into monomers by greater amounts of nonionic detergent

Fig. 1 Protein oligomers with n -fold rotational symmetry axis consisting of 2, 3 and 4 identical subunits. The repeating interfaces between the subunits are designated k and l .

Table 1 Some oligomeric transmembrane proteins

Protein	Source	Molecular weight ($\times 10^3$)		Type	Evidence (ref.)
		Monomer	Oligomer		
ADP/ATP carrier	Mitochondria: animal and <i>Neurospora crassa</i>	30 34	60 68	α_2 α_2	Inhibitor binding (21, 69) Cross-linking (17, 69) Hydrodynamic (17)
Uncoupling protein	Brown adipose tissue (mammalian)	32	64	α_2	Hydrodynamic (19)
($\text{Na}^+ + \text{K}^+$)ATPase	Plasma membrane, for example, shark rectal gland	—	330	$(\alpha\beta)_2$ $(\alpha\beta_2)_2$	Cross-linking (7) Hydrodynamic (24, 25)
Ca^{2+} -ATPase	Sarcoplasmic reticulum	100	400	α_4	
Anion carrier (band III)	Erythrocytes	90	180	α_2	Cross-linking (5)
Glucose carrier	Erythrocytes	55	100	α_2	Freeze-etching counts (33) Inhibitor binding (33, 70)
Galactoside carrier	<i>E. coli</i>	30, 44?	—	α_2	Cited in ref. 71
Porin	<i>E. coli</i> , outer membrane	37	—	α_3	Electron diffraction (72)
Bacteriorhodopsin	<i>Halobacterium</i>	28	—	(α_3)	Electron diffraction (28)
Acetylcholine receptor	Electric organ: <i>Torpedo</i>	250	500	$(\alpha\beta \dots)_2$	Hydrodynamic (73) Disulphide formation (74)
Cytochrome <i>b</i>	Mitochondria: animal and <i>N. Crassa</i>	30	60	α_2	Hydrodynamic (10)
Cytochrome <i>bc_1</i> -complex	Mitochondria	—	420	$(\alpha_2\beta \dots)_2$	Hydrodynamic (18, 22)
Cytochrome oxidase	Mitochondria	110	345	$(\alpha\beta \dots)_2$	Hydrodynamic (23)

without loss of ATPase activity²⁶. In contrast, rhodopsin occurs as a monomer both in the membranous and isolated states²⁷. The diffusibility of this protein as part of its function is in agreement with its monomeric state. Bacteriorhodopsin, which forms a crystalline purple membrane lattice²⁸, is also monomeric in detergent solution²⁹, although electron diffraction indicates trimer formation in the membrane.

Another fact which strongly supports dimeric structures comes from ligand binding studies, using highly specific inhibitors of translocators. The frequent result of such experiments is that only half a binding site exists per protein subunit: that is, a complete binding site requires at least a dimer of the protein subunits. Examples are the binding of ouabain to ($\text{Na}^+ + \text{K}^+$)ATPase³⁰ (see however ref. 31), the binding of atractylate or bongkrekate to ADP/ATP carrier^{21,32} and cytochalasin B binding to the glucose carrier³³.

There is evidence that the dimeric structure in the isolated protein is the native one for the ADP/ATP carrier as it loses ligand binding affinity on forming monomers. Only in the dimeric form does the cytochrome *bc_1* complex show succinate-cytochrome *c* reductase activity²². The ($\text{Na}^+ + \text{K}^+$)ATPase is reconstitutionally active when isolated with nonionic detergent as a dimer³⁴.

To conclude, note that some oligomeric membrane proteins have a rather cryptic transport function for ions: for example, cytochrome complexes may pump H^+ (ref. 35), various ATPases pump H^+ , Na^+ or Ca^{2+} , the acetylcholine receptor has a Na^+ channel³⁶, and the uncoupling protein of mitochondria catalyses anion transport³⁷.

Structural principles of oligomeric membrane proteins

Further analysis of the implications and characteristics of the oligomeric structure of membrane proteins requires a brief resumé of some general principles of oligomer formation. Much has been published on the symmetry properties of oligomeric enzymes and their functional consequences³⁸⁻⁴⁰, therefore these problems will be discussed only with regard to the particular situation of membrane proteins. Figure 1 shows some oligomers with 'C'-type symmetry. A closer look at the geometrical principle of association is important for understanding the characteristics of these structures. Dimeric and trimeric proteins can form only one type of symmetrical oligomer which is characterized by a C_2 - and C_3 -rotational axis. Tetramers can form several symmetrical structures; the oligomer with C_4 symmetry corresponds to those of the dimers and trimers. Higher symmetry of the D_2 type is found in many soluble tetrameric proteins. For reasons discussed below, this arrangement is

unlikely for tetrameric membrane proteins. Tetramers can also be visualized as being arranged in pseudo- C_4 symmetry and strict C_2 symmetry when two dimers associate to form a tetramer by retaining their original dimeric structure.

One point of discussion concerning oligomeric structure is that of isologous versus heterologous association and the relationship of this to cooperative effects between the subunits^{41,42}. Regarding this differentiation, only the dimer would be isologous whereas the C_3 -trimer and the C_4 -tetramer are heterologous. This differentiation, however, can be dismissed in analysing the contact area between the subunits in these oligomers. Each subunit may be thought to have a k- and an l-surface separated by the symmetry axis; in all three cases the k-surface associates with the l-surface of the other subunit in an 'heterologous' manner. This is true for the dimer in much the same way as for the trimer and tetramer. There is no particular distinction in the 'isologous' association of the dimer over those of the trimer and tetramer. In fact, one of the main advantages claimed for isologous as compared with heterologous association, which applies to all three cases, is that a mutation which changes the interface will be effective on both sides of the C-axis in the oligomer.

Oligomer membrane proteins and phospholipid bilayer

Membrane proteins are generally assumed to have a hydrophobic surface in those areas which make contact with the membrane lipid layer. The share of the hydrophobic surface should be particularly large in proteins deeply imbedded in the membrane, the most prominent example of which are carriers

Fig. 2 Interaction of a dimeric protein with the asymmetric phospholipid bilayer. The localization of a dimer with the 2-fold axis either normal or parallel to the membrane plane. The surfaces of the protein are designated by p and q and the phospholipid bilayers by m and n.

such as those for ADP and ATP or glucose. The high amount of Triton binding to these proteins has been thought to reflect the extensive membrane contact area⁴³. However, the amount of detergent bound cannot be used as a measure of the hydrophobic region because of the tendency of nonionic detergents to form micelles at these surfaces⁴⁴.

The 'specific' interaction between subunits should be contrasted with nonspecific association often encountered in membrane proteins resulting from the interaction of the hydrophobic surfaces. This aggregation can occur if the isolated protein lacks sufficient detergent. The size of the aggregation may reach microscopic dimensions or it may be limited and even well defined, for example, in protein micelles with a hydrophobic core.

How are oligomeric membrane proteins arranged in the membrane? Biomembranes are topologically asymmetric for the obvious reason that they separate spaces of different composition. There is a prominent asymmetry between both leaflets of the lipid bilayer caused by asymmetric distribution of membrane phospholipid⁴⁵. The asymmetric assembly of the membrane can also include the membrane proteins. For the oligomeric transmembrane protein an arrangement with the rotational axis normal to the membrane is the obvious choice. This arrangement might be stabilized by interaction with the asymmetric bilayer, particularly by the different phospholipid head groups which can interact with the membrane protein through ionic forces.

Due to the interaction between phospholipids and protein, a transmembrane axial arrangement is energetically more favourable than the symmetrical arrangement with the axis within the membrane plane. This can be illustrated (Fig. 2) by summing up the free energy changes associated with the interaction of specific protein surfaces and phospholipid regions of the asymmetric bilayer. The free energy change for the transmembrane axial case (ΔG_T) can be described as being equivalent to $(np + mq) \times 2$ (see Fig. 2 legend for explanation of symbols) whereas the free energy change for the parallel axis would be $\Delta G_P = np + mq + nq + mp$. Assuming that $np + qm$ is the preferred interaction (a free energy minimum), for example, $np + qm > nq + mp$, it follows that $\Delta G_T > \Delta G_P$. These arguments are valid only for oligomeric proteins and we can conclude that the asymmetric transmembrane axial arrangement provides the membrane proteins not only with maximum interaction forces with phospholipids but also with additional stabilization of their quaternary structure.

After solubilization of membrane proteins in detergent, the asymmetric environment is abolished. By replacing the phospholipid bilayer, nonionic detergents form a micelle around the protein⁴⁴. In general the detergent will be asymmetrically distributed around the protein, but the uniform detergent does not allow a differential binding of molecules to different parts of the protein. The absence of this differentiation may contribute to the relative instability of detergent-solubilized proteins.

Membrane multicomponent complexes

A clear example of a C_2 -transmembrane arrangement of a dimeric membrane protein is the $(Na^+ + K^+)$ -pump (see also ref. 46). The sections responsible for ATP hydrolysis in both subunits must be directed towards the cytosolic face and electron microscopy shows that $(Na^+ + K^+)$ ATPase (and Ca^{2+} -ATPase⁴⁷) bulge only towards the inner side of the cell. Each large subunit of the $(Na^+ + K^+)$ ATPase binds a minimum of one 53,000 molecular weight (M_r) glycoprotein which faces the extracellular space^{31,48}.

In C_2 -transmembrane multicomponent proteins the subunits can be expected to be attached asymmetrically to the membrane, because identical intersubunit binding sites follow the transmembrane axis. Thus, in membrane-bound multi-enzyme complexes, subunits will be aligned in such a way that they form a C_2 -symmetric complex. Often only one or two of the peptides are imbedded in the membrane, the other subunits being attached to the surfaces protruding from the membrane,

Fig. 3 Common central or separate channels and the binding centres in dimeric transport proteins.

for example in the ATP-synthase of mitochondria. Conversely, the existence of detachable subunits on one side of a membrane protein can be considered as evidence for C -type symmetry. For oligomeric membrane-bound glycoproteins, a transmembrane asymmetry is obligatory as the glycoside moiety is always directed towards the outer surface of the organelle membrane. This is the case, for example, with the anion channel of erythrocytes which is a dimer of two identical transmembrane glycoprotein subunits^{48,49}. Glycophorin may also form a transmembrane dimer in the erythrocyte, although no clear evidence has been reported⁵⁰.

Oligomeric structure and transport

So far we have seen that membrane proteins may acquire certain structural advantages unavailable to soluble proteins by forming oligomers in their hydrophobic environment. Do they also derive functional benefits from the oligomeric, axial transmembrane arrangement?

Translocation of hydrophobic molecules through the membrane requires a hydrophilic channel. Relatively rigid channels extending through the membrane exist in permanent forms to allow, for example, the nonspecific passage of solutes. Closely related to such pores are the gated channels through which, when open, many molecules or ions may diffuse. For the usual carrier-mediated transport, however, the channel should close or open during each turnover when one molecule or a defined set of ions is being moved through the membrane. In this case, the channels are highly flexible and gated so that at no instance do they freely extend across the whole membrane.

Binding forces between subunits are at a minimum along the symmetry axis because identical amino acid residues oppose each other. This should facilitate formation of a straight channel along the symmetry axis and corresponding pores have indeed been observed at atomic resolution for dimeric and tetrameric enzymes. With a transmembrane arrangement of the symmetry axis, a channel across the membrane could be formed in an oligomeric membrane protein (Fig. 3). Furthermore, this channel might have a hydrophilic surface as in membrane proteins a hydrophilic subunit interface may be energetically more favoured in the formation of oligomers, in view of the hydrophobic outer surface.

It has been tempting to suppose that membrane-bound carriers use the intersubunit channel as a translocation path for the substrate^{46,51} but experimental evidence in favour of such a model has only recently been obtained. The gated pore model was suggested from studies on the dimeric ADP/ATP carrier⁵², as will be discussed below. The alternative view has been that each subunit forms a separate channel. These channels could run either inside each subunit or at the interface (Fig. 3). However,

outside the symmetry axis, *a priori*, no straight path can be expected to occur.

Experimental data from exchange type systems⁵² suggest an intersubunit translocation path. (This is rather surprising because *a priori*, a reciprocating or 'flip-flop' mechanism of the two subunits would be the more obvious.) Two cooperating parallel channels are required for the simultaneous release and uptake of the exchange molecules. A dimeric carrier seems to be an obvious choice for this although alternatively the exchange could function in a sequential manner, often denoted as a 'ping-pong' mechanism. Each channel operates by facilitating, in turn, the uptake and release of a substrate molecule. The ping-pong performance is controlled by the gates in the channel. This exchange system differs from the unidirectional transport in that the gate can function only when the substrate is present. Either the common channel or the separate channels in a dimer could function by this process. Experimental evidence is largely in favour of this mechanism as opposed to the reciprocating model^{53,54}.

Binding sites and gates of the carrier

The translocation apparatus requires, besides the channel, a binding site for the substrate and a closely linked gate. It is the study of the binding sites that has so far produced the most valuable information concerning carrier mechanisms, for it is the binding sites of carriers which determine the high specificity of transport. It becomes abundantly clear from specificity studies that the binding of the transported molecule immediately triggers the transport reactions, presumably by means of conformation changes which open the channel gates. Substrate analogues or 'inhibitors' may bind with even higher affinity but have little or no triggering power.

In dimeric carriers, the two binding sites may be separated (Fig. 3), in which case the separate translocation paths would be imbedded within the subunits. With a central channel, the binding sites would directly face each other at the C_2 -axis and as a result, binding of one ligand should prevent that of the other. In fact, as shown above, in several dimeric carriers, binding of only one substrate or inhibitor per dimer has been observed.

The behaviour of some dimeric or tetrameric enzymes, in which negative cooperativity between the subunits controls binding and catalytic activity^{55,56}, has been called 'half-site' reactivity^{40,57}. Is the observed 'half-site' binding of carriers due to a similar effect? If so, little would be gained for dimeric carriers with separate channels, except for a decrease in transport activity. However, for the counter-exchange, 'half-site' reactivity would have a purpose if it generated a reciprocating

transport, which would be analogous to the flip-flop activity elaborated in detail for some half-site enzymes⁵⁷. The two binding sites are directed to opposite membrane sides and thus alternate between binding and releasing substrate to opposite sides. A flip-flop model has been discussed in detail for the $(Na^+ + K^+)ATPase$ ⁵⁸. Most of the evidence for $(Na^+ + K^+)ATPase$, however, is against counterflow and in favour of a sequential $(Na^+ + K^+)$ -exchange.

In the central channel model half-site reactivity becomes a trivial sterical consequence as the two binding sites face each other. Binding of one substrate molecule would sterically prevent binding to the second site, particularly if the substrate is relatively large. As a result, functional asymmetry between both subunits is induced, which may further generate some conformational asymmetry.

The translocation process

The actual translocation process can be accommodated by assuming an alternating gating of the channel around the binding site such that the binding site is opened either to the internal surface of the membrane, when the carrier is said to be in the 'i' state, or to the external surface, when the carrier is in the 'e' state. In the case of an axial binding centre, the states are distinguished by a positional shift between the two subunits such that gates are closed or opened at the interface. With separate channels, a conformational change inside each subunit during the transition would be required and the gating can be thought of as being caused by positional shifts between the protein lobes around the channel or by discrete shifts of only one or two amino acid residues.

Evidence at the molecular level for the two translocational states of the carrier was first deduced by studying the binding site of the ADP/ATP carrier⁵². The transition between the 'e' and 'i' state (in that instance, 'c' = cytosolic state and 'm' = matrix state) had a strict requirement for substrate binding and as predicted, the binding centre was shown never to face both sides of the membrane simultaneously. These conclusions were fully corroborated with the solubilized, purified ADP/ATP carrier^{53,59}.

The radical change in specificity for the inhibitors of the binding centre on the transition between the 'c' and 'm' state has been interpreted, as illustrated in Fig. 5, to reflect the existence of a fixed rather than a rotational carrier⁵⁴. With the former an asymmetric substrate should, on entering the binding centre from one side, interact with the protein through a different face than on leaving from the opposite side. By contrast, with a rotational carrier the relative position of substrate to carrier should not be changed; in a stationary carrier the binding surface of the protein state should differ from that in the 'e' state so that there is a drastic difference in specificity. That is precisely what is seen with the ADP/ATP carrier which specifically binds atracylate in the 'c' state but bongkredate in the 'm' state, whereas the affinity for the substrates remains largely unchanged⁴⁷. Similarly, the glucose carrier in erythrocytes binds cytochalasin B only from inside⁶⁰ and binds various steroids asymmetrically from inside and out⁶¹; the Na^+ -dependent glucose carrier has a different ordered binding sequence for Na^+ and glucose on the sides⁶²; and the $(Na^+ + K^+)ATPase$ exhibits affinity changes for Na^+ and K^+ in the E_1 and E_2 state (although here the superimposition of an ATP-driven transition complicates the same principle).

The model of Fig. 5 requires that a single binding site changes its specificity between the 'i' and 'e' states of the carrier. Alternatively there are two different binding sites in series along the channel, either axial or intrasubunit, with the substrate migrating between the two sites (Fig. 4). The different specificity would then result from the dissimilar configuration of the 'i' and 'e' site located in dissimilar regions of protein. However, from a comparative viewpoint this seems improbable because enzymes generally contain only one binding centre per subunit, with second centres being regulatory.

A configurational change in a binding site between the 'i' and 'e' state implies that a partially different set of amino acid

Fig. 4 Alternative 'gated pore' models of membrane carriers. With a single central channel the binding centre opens either to the outside (e-side) or inside (i-side) primarily by repositioning of the two subunits. For separate channels the gating requires intrasubunit conformational change.

Fig. 5 The difference in flexibility of the binding centre in a rotational and fixed carrier⁵².

residues participates in the binding in the two states; the consequential change of affinity for the substrates could be beneficial in unidirectional transport. On the other hand, in counter-exchange, the binding affinities for the substrate would need to be well balanced, with energy-driven transport perhaps being achieved by a superimposed imbalance of the binding affinities in the two states. Evidence for the ADP/ATP carrier indicates that energy, as exerted by a membrane potential, does not change affinities but rather the distribution between the 'i' and 'e' states^{63,64}.

In trying to distinguish between the various models for translocation shown in Fig. 4, perhaps the best evidence for several dimeric carriers is that they bind only one molecule of substrate or inhibitor. Although this is still compatible with the existence of two separate channels in which the second site is inhibited by negative cooperativity, it seems unlikely because it has not been possible to increase binding at the ADP/ATP carrier by abolishing negative cooperativity, for example by monomerization of the carrier.

Another important observation is the conformational change on transition between the 'i' and 'e' state. This is most compatible with the central channel model where both subunits change conformation between the 'i' and 'e' state in parallel. More complicated assumptions must be made for the two-channel

model: conflicting cooperativity is required, a negative one to lock the other binding centre, and a positive one to synchronize the conformational transition between the binding and non-binding subunits. Furthermore, the reciprocating (flip-flop) model can be discounted because it requires that one subunit always exists in the 'i' state and the other in the 'e' state.

Most of these constraints are abolished if there are independent separate channels. In that case both binding sites of dimeric carriers should be active. Evidence for that exists for the anion carrier of erythrocytes⁶⁵ and the galactoside carrier of *Escherichia coli*⁶⁶ but has yet to be confirmed for the purified native protein.

Dimeric membrane proteins with other than transport functions, such as cytochrome complexes in mitochondria, also seem to show half-site reactivity. For example, cytochrome *b*, being a dimer in the cytochrome *bc*₁ complex, reacts as if there are two different species of cytochrome *b*. An anti-cooperativity between two identical cytochrome *b* molecules has been invoked for an alternating H⁺-pumping activity of cytochrome *b* in the redox cycle⁶⁷. A similar suggestion has been derived by Wikström⁶⁸ for the cytochrome oxidase complex. Note, however, that another H⁺-pump, bacteriorhodopsin, seems to operate with independent channels in each subunit. This can be reconciled with the fact that interaction between bacteriorhodopsin trimers in the hexagonal crystalline arrangement of the purple membrane is rather weak.

Conclusions

Oligomeric structures seem to be particularly well suited to integral membrane proteins which have carrier functions. The obvious role in transport of many integral proteins requires channels extending through the protein either along the *n*-fold axis or inside each subunit. The channels may be gated during each substrate turnover as in typical carrier-mediated transport. The catalytic binding centre in the channel of a number of dimeric carriers exhibits half-site reactivity which can be interpreted either as negative cooperativity for separate channels or as steric overlap in a common axial channel. Gating, as triggered by substrate binding, opens the site to the inside and outside, in turn. As a result the specificity of the carrier to inhibitor ligands is drastically changed in accordance with the direction in which transport is proceeding, for a stationary carrier. The parallel conformational change of both subunits between the 'e' and 'i' state, together with the half-site binding, can best be explained in terms of a single centre axial channel.

The 'braided' F-ring of Saturn

Stanley F. Dermott

Center for Radiophysics and Space Research, Space Sciences Building, Cornell University, Ithaca, New York 14853, USA

The larger of the two satellites which bound the F-ring of Saturn could have only one first-order resonance within the ring. If such a resonance exists, then a wave pattern of equally spaced loops which co-rotate with the satellite will be excited. This pattern could account for the braided appearance of the ring.

GOLDREICH AND TREMAINE¹ consider that particles in the narrow rings of Uranus are confined by tidal torques exerted on their orbits by small, unseen, satellites. The recent discovery by Voyager 1 of two small satellites, S13 and S14, which bound the narrow F-ring of Saturn², seems to confirm this view. However, the structure of the F-ring is complex and quite unlike that of the ϵ ring of Uranus. Some of the images of the F-ring show two bright rings which appear to be intertwined or braided. These two rings are closely associated with a third, but this is very diffuse (see Fig. 1)³. We show here how gravitational perturbation of the ring particle orbits by S13 and S14 may not only account for the confinement of the ring particles but may also explain some of the 'braided' structure of the F-ring.

Tidal torques

The tidal torque exerted on a narrow ring of particles of total mass m_r by a nearby satellite of mass m can be estimated from the scattering angle δ in Fig. 2b (ref. 4).

$$\delta = \frac{2Gm}{xU^2} \quad (1)$$

where the relative velocity U is given by

$$U = \pm \frac{3}{2}nx \quad (2)$$

G is the gravitational constant, n is the mean motion of the ring particles and x is the separation of the satellite and the ring. Since the tangential component of the relative velocity is reduced from U to $U \cos \delta$, angular momentum is exchanged with the net result that the ring experiences a torque

$$T = \pm \frac{4}{9\pi} \left(\frac{Gm}{nx^2} \right)^2 m_r \quad (3)$$

The sign of the torque depends on whether the satellite is on the inside or the outside of the ring and is such that the satellites repel the ring particles¹.

If a ring is bounded by two satellites, then its width will be reduced until the confining torques just counteract the tendency

of the ring to spread due to particle collisions. The equilibrium width of the ring is

$$W \sim \left(\frac{3\pi\tau}{4} \right)^{1/2} \left(\frac{x}{r} \right)^{5/2} \left(\frac{M}{m} \right) d \quad (4)$$

where M is the mass of the planet, r is the radius of the ring and d is the characteristic diameter of those particles which determine the spreading rate¹. τ is not simply the optical depth of the ring, this is always determined by the number density of the smaller particles, but the optical depth that the ring would have if all particles of diameter $< d$ were removed. For the F-ring of Saturn

$$d \sim \frac{40}{\tau^{1/2}} \left(\frac{30 \text{ km}}{W} \right) \left(\frac{m/M}{9 \times 10^{-9}} \right) \left(\frac{1,000 \text{ km}}{x} \right)^{5/2} m \quad (5)$$

($m/M \sim 9 \times 10^{-9}$ corresponds to a satellite of diameter 200 km and density 1.2 g cm^{-3} .) If Goldreich and Tremaine are right, then the F-ring must have a substantial population of large particles. However, we consider that equation (3) may overestimate the magnitudes of the confining torques.

When the ring is in equilibrium, the torques due to the satellites must be equal and opposite, hence, from equation (3),

$$\frac{m_o}{x_o^2} = \frac{m_i}{x_i^2} \quad (6)$$

where subscripts o and i refer to the outer and inner satellite respectively. For the purposes of this article, it is sufficient to assume that the satellites and the ring particles move in coplanar, circular orbits.

Standing waves

Because $x \ll r$, the gravitational force on a ring particle due to a satellite is only effective at close encounters. During encounter, a particle initially moving in a circular orbit, acquires a radial velocity $U \sin \delta$ and thereafter moves in a keplerian ellipse of eccentricity

$$e \sim \frac{U \sin \delta}{nr} = \frac{4}{3} \frac{m}{M} \left(\frac{r}{x} \right)^2 \quad (7)$$

Fig. 1 This image, taken at a range of 750,000 km by Voyager 1, shows the highly complex structure of Saturn's F-ring. Two narrow 'braided' bright rings that trace distinct orbits are evident. Visible is a broader, very diffuse component, about 35 km wide. Also seen are 'knots' which are probably local clumps of ring material, but may be small satellites. Image courtesy JPL/NASA.

(see Fig. 2). A more accurate calculation by Julian and Toomre⁵ shows that the coefficient in this equation is 2.24 and not 4/3.

In a frame co-rotating with the perturbing satellite, all particles initially moving in circular orbits must follow identical paths after encounter. Thus each satellite generates a standing wave of amplitude

$$A = er \quad (8)$$

and wavelength

$$1 = \frac{2\pi U}{n} = 3\pi x \quad (9)$$

(see Fig. 2). In the inertial frame, each particle moves in an independent keplerian ellipse, but the pericentres of these elliptical orbits and the phases of the particles on the orbits are such that the locus of the particles is a sinusoidal wave which moves through the ring with the angular velocity of the perturbing satellite.

Because the tidal torques on the ring are equal, it follows from equations (6) and (8) that the amplitudes of the two waves are equal. For the F-ring of Saturn

$$A \sim 54 \left(\frac{m/M}{9 \times 10^{-9}} \right) \left(\frac{1,000 \text{ km}}{x} \right)^2 \text{ km} \quad (10)$$

and may be comparable with the width of the ring ($W \leq 30 \text{ km}$) (ref. 3). The interaction of these two waves, which probably have quite different wavelengths, could produce novel phenomena such as beats.

Resonance

Because $W \ll x$, the perturbations of the ring particle orbits will be highly coherent and although particle collisions will act to damp the waves, the process may be slow (and for this reason the magnitude of the torque given by equation (3) may be an overestimate). If the waves can survive from one encounter to the next, then we must consider the possibility of resonance.

This will occur if the ring circumference is an integral number of wavelengths, that is, if

$$\frac{2r}{3x} = p + 1 \quad (11)$$

where p is an integer. Consecutive perturbations will then be in phase and a wave of amplitude significantly greater than A may result.

The exact resonance condition can also be written

$$\frac{n'}{n} = \frac{p}{p+q} \quad \text{or} \quad \frac{p+q}{p} \quad (12)$$

where n' is the mean motion of the perturbing satellite and $q = 1$ for the type of resonance (first-order) that we are considering. As p can take any integral value ≥ 1 , a large number of resonances may occur. These are separated by a radial distance s , where

$$s = \frac{3}{2} \frac{x^2}{r} \quad (13)$$

For the satellites which bound the F-ring,

$$x_o \sim 2,500 \text{ km} \quad (14)$$

$$x_i \sim 800 \text{ km} \quad (15)$$

(ref. 2). Hence

$$s_o \sim 68 \left(\frac{x_o}{2,500 \text{ km}} \right)^2 \text{ km} \quad (16)$$

and

$$s_i \sim 7 \left(\frac{x_i}{800 \text{ km}} \right)^2 \text{ km} \quad (17)$$

These two sets of resonances will have quite different strengths. The amplitudes of the waves generated by a single encounter will be equal, but the larger satellite, which must be more distant

Fig. 2 Confinement of a narrow ring by two small satellites¹. *a*, Angular velocity decreases with increasing distance from the planet. Thus ring particles leading the outer satellite and lagging the inner satellite will be forced to move in eccentric orbits. Waves are excited which co-rotate with the perturbing satellite. *b*, The amplitude of the waves can be estimated from the scattering angle δ (ref. 2).

from the ring than the smaller satellite (see equation (6)), will have the larger relative velocity U and the time between encounters will be correspondingly shorter. Thus one would expect the resonances associated with the larger, outer satellite to dominate the structure of the ring. But these resonances are separated by a distance which is greater than the width of the ring. Thus, this satellite could have one, but only one, first-order resonance within the ring. The other possibility is that the width of the ring is < 7 km, and that a single first-order resonance associated with the smaller satellite exists within the ring.

For particles close to the exact resonance, the resonance condition is

$$pn - (p+1)n' + \dot{\omega} = 0 \quad (18)$$

where $\dot{\omega}$ is the pericentre of a ring particle orbit. If the particle is locked in resonance, and the forced eccentricity is small, then the pericentres of the ring particle orbits are not aligned, rather $\dot{\omega}$, $\dot{\omega}'$ and the mean longitude, or phase, are such that conjunctions of a particle and the satellite always occur at an apse of that particle's orbit⁶. The magnitude of the forced eccentricity, in the absence of damping, is given by⁶

$$e = \left| \frac{1/2(m/M)f(p)n'}{(p+1)n' - pn} \right| \quad (19)$$

Thus e increases markedly as the exact resonance is approached. At the exact resonance, the phase of the response changes by 180° . Similar behaviour is observed in any driven harmonic oscillator. For particles outside the exact resonance conjunction always occurs at apocentre, whereas for particles on the inside of the exact resonance conjunction always occurs at pericentre. Thus, the satellite excites a wave pattern of equally spaced loops which co-rotate with the perturbing satellite (see Fig. 3).

If p is large, then the inside width W_1 of a loop, that is, the maximum width of the gap generated in the ring, is given by⁷

$$W_1 = 2.96 \left(\frac{m}{M} \right)^{1/2} r \quad (20)$$

Thus, the effect of a given first-order resonance is determined solely by the mass of the perturbing satellite and is independent of both p and x . For the F-ring of Saturn,

$$W_1 = 39 \left(\frac{m/M}{9 \times 10^{-9}} \right)^{1/2} \text{ km} \quad (21)$$

The magnitude of this gap should be compared with the amplitude A of the short-period perturbations (see equation (10)). Two regimes can be clearly identified. If $A \gg 1/2 W_1$, then loop formation will be forever frustrated by the large perturbations suffered by the ring particles at each passage of the perturbing satellites. However, if $1/2 W_1 \gg A$, then loop formation is inevitable.

From equations (10) and (20), it follows that for $1/2 W_1 > A$, we must have

$$p < 56 \left(\frac{9 \times 10^{-9}}{m/M} \right)^{1/4} \quad (22)$$

or

$$x > 1,700 \left(\frac{m/M}{9 \times 10^{-9}} \right)^{1/4} \text{ km} \quad (23)$$

Thus, provided that the perturbing satellite is not so distant that first-order resonance is not possible, that is, provided that

$$\frac{n'}{n} > \frac{1}{2}, \quad (n' < n) \quad (24)$$

then the more distant the perturbing satellite the more likely is loop formation. However, if the unperturbed width of the ring is W , then the probability P that a first-order resonance will exist

Fig. 3 Ring particle paths in a frame co-rotating with the perturbing satellite. Resonant gravitational interactions at radii in the ring where the ratio of the satellite and ring particle mean motions are close to $p/(p+1)$, where p is an integer, generate a system of waves which are stationary in the rotating frame. The waves on opposite sides of the exact resonance have a phase difference of 180° , hence the resultant wave pattern consists of $p+1$ equally spaced loops. This could account for the braided appearance of the F-ring of Saturn.

within the ring is given by

$$P = \frac{W}{s} = \frac{2rW}{3x^2} \quad (25)$$

and for the F-ring of Saturn,

$$P = 0.96 \left(\frac{W}{30 \text{ km}} \right) \left(\frac{1,700 \text{ km}}{x} \right)^2 \quad (26)$$

This suggests that loop formation is both possible and likely for satellites more distant than 1,700 km but not more distant than, say 5,000 km. According to early Voyager 1 reports², S13 orbits 2,500 km outside the F-ring, thus I consider that it is this satellite which is responsible for the 'braiding' of the F-ring.

Resonance is necessary to produce the bifurcation of particle orbits which is the essence of loop formation. The resonance need not be in the middle of the ring, in which case the two 'braids' will not necessarily be of equal brightness. Also, the short-period perturbations will not be negligible and, if the satellite orbits are not perfectly coplanar with the mean ring plane, waves both in the plane and out of the plane will be continuously excited by these satellites. The passage of these waves through the loops will give rise to shock phenomena associated with close-packing of ring particles⁷ and, possibly, because the ring is probably just outside Roche's limit for satellite formation, the formation of temporary particle clumps. Furthermore, because of these waves, the length and shape of

the loops will continuously change, and the structure of the ring, although periodic, will be highly complex and variable.

This theory cannot account for the third, diffuse ring. Perhaps this ring consists of small (micrometre-sized) particles which are generated in the main ring by erosion due to sputtering and meteoroid impacts and then removed by electromagnetic forces.

This article was inspired by comments from P. Goldreich and S. Tremaine during the Voyage 1 Saturn encounter. I thank C. D. Murray, R. Farouki and T. Gold for useful contributions. The data are from early Voyager Bulletin Mission Status Reports and I thank the Voyager Imaging Team (leader B. A. Smith) for

their generosity in releasing this information before their own publication. This research was supported by NSF grant AST 79164-74-A01.

Sequence and organization of the human mitochondrial genome

S. Anderson, A. T. Bankier, B. G. Barrell, M. H. L. de Bruijn, A. R. Coulson, J. Drouin*, I. C. Eperon, D. P. Nierlich*, B. A. Roe*, F. Sanger, P. H. Schreier*, A. J. H. Smith, R. Staden & I. G. Young*

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

The complete sequence of the 16,569-base pair human mitochondrial genome is presented. The genes for the 12S and 16S rRNAs, 22 tRNAs, cytochrome c oxidase subunits I, II and III, ATPase subunit 6, cytochrome b and eight other predicted protein coding genes have been located. The sequence shows extreme economy in that the genes have none or only a few noncoding bases between them, and in many cases the termination codons are not coded in the DNA but are created post-transcriptionally by polyadenylation of the mRNAs.

MITOCHONDRIA have a separate autonomously replicating DNA genome (for a review see ref. 1). Although most of the proteins present in the mitochondrion are encoded by nuclear DNA, a few are coded for by mitochondrial (mt) DNA and are synthesized by the separate mt translation system. The rRNAs and tRNAs of this system are mitochondrially encoded and it is likely that the other components, although nuclear coded, are distinct from those in the cytoplasmic translation system. The enzymes specific for the unique mitochondrial transcription and replication processes are probably also nuclear coded. We have recently shown that mammalian mitochondria have a different genetic code^{2,3} as have other mitochondria systems that have been studied⁴⁻⁷, and a different decoding mechanism⁷⁻⁹.

Replication of mammalian mtDNA proceeds by initiation of heavy (H) strand synthesis at a specific origin^{10,11} resulting in the formation of a displacement (D) loop with a newly synthesized H strand of ~680 bases known as 7S DNA. In mouse cells a large proportion of mtDNA exists in the D-loop form but only a few of these nascent H strands grow to full length. Initiation of light (L) strand synthesis is at a specific origin¹² and does not occur until this region has been exposed by H-strand synthesis.

Transcription of mammalian mtDNA is also unique in that both strands seem to be completely transcribed from promoters situated in the D-loop region^{13,14}. These primary transcripts are then processed to give the 12S and 16S rRNAs, tRNAs and a number of presumptive mRNAs, which are not capped but are polyadenylated¹⁵. The small size of the ribosomal RNAs, the chloramphenicol sensitivity of mitochondrial protein synthesis and the use of formyl-methionine in initiation of translation

have led to the suggestion that the mitochondrial genetic system arose by endosymbiosis of primitive bacteria within a host cell. The sequence of the rRNA genes, however, shows only low homology with present-day prokaryotic rRNAs¹⁶.

To understand this genetic system more fully we have determined the complete DNA sequence of both the human and the bovine mitochondrial genomes. We report here the sequence of human mtDNA and an interpretation of this sequence in terms of its coding capacity, gene arrangement and gene expression. The bovine sequence will be published elsewhere.

In the accompanying articles Ojala *et al.*¹⁷ and Montoya *et al.*¹⁸ report the sequence analysis of the stable polyadenylated RNAs. The comparison of the DNA and RNA sequences reveals the unique nature of the precise transcript processing in mammalian mitochondria.

Organization of the genome

The DNA sequence is shown in Fig. 1 along with the predicted coding sequences. This is presented schematically in Fig. 2. The identification of the genes and their precise location in the DNA sequence are based on several unique features, the evidence for which is discussed below and in the accompanying articles^{17,18}. The sequence shows extreme economy of organization in that there are none or very few noncoding bases between adjacent genes except for the D-loop region where we have been unable to assign any coding function. The sequence shown is that of the L strand which we define as the main coding strand containing the sense sequence of the rRNAs and most of the tRNAs and mRNAs. Thus, these RNAs are transcribed from (and therefore hybridize to) the H strand.

Origins of DNA replication

The 5' end of the major 7S DNA species found in the D-loop of HeLa cell mtDNA¹⁰ corresponds to nucleotide 191 of the DNA sequence. Other human 7S DNA species having different 5' ends have also been reported^{11,19,20}, but the precise location of these termini in the sequence presented here is not known. The size of the 7S DNA (≤ 680 nucleotides) and mapping data^{10,19,20}

The genetic code of human mtDNA differs from the universal code in that UGA codes for tryptophan and not termination, AUA codes for methionine not isoleucine, and AGA and AGG are termination rather than arginine codons. In addition, AUA and possibly AUU are initiation codons as well as AUG. Boxes of four codons are each read by a single tRNA with U in the first position of the anticodon; boxes of two codons are read by tRNAs with G:U wobble anticodons. The number of methionyl tRNAs and their codon response are unclear and discussed in the text. Also shown are the total number of each amino acid codon found in the genes and predicted genes shown in Figs 1 and 2. Codons ending in A and C predominate (36.37 and 40.93%, respectively) and those ending in U and G are used less frequently (16.33 and 6.36%, respectively).

indicate that the 7S DNA, and presumably the D-loop, do not extend into the tRNA^{Pro} gene. Although H-strand synthesis during replication initiates in the D-loop region, data from mouse cell mitochondria indicate that most of the 7S DNA molecules do not participate in DNA replication but rather are synthesized and then rapidly lost from the D-loop²¹.

The ~1,100-base pair region of the human mitochondrial genome between the tRNA^{Pro} and tRNA^{Phe} genes contains no large open reading frames in either strand. Furthermore, except for a small 7S RNA¹⁵, no large stable polyadenylated transcript has been found to map in this region. Unless RNA splicing is invoked it is extremely unlikely that this part of the genome codes for a major protein species. In the region covered by the D-loop, several blocks of nucleotide sequence homology exist between the human, bovine (S.A. *et al.*, unpublished results) and rat mitochondrial genomes²². However, the DNA separating these blocks is rather variable in length and exhibits no significant homology. The region between the 5' end of the 7S DNA and the tRNA^{Phe} gene seems to be one of the least conserved regions of the entire genome. This was initially detected by electron microscopy of heteroduplexes of sheep and goat mtDNAs²³ and has been confirmed by the DNA sequence comparisons. Very little sequence homology between the human, rat²² or bovine mitochondrial genomes can be detected in this region. The size of the region also seems to vary much

more than do intergenic spaces in other parts of the mtDNA, being 385 nucleotides in the human placenta, 291 nucleotides in rat liver and (based on alignment with the human and rat sequence) ~180 nucleotides in beef heart. This region may contain control signals for transcription of the mitochondrial genome.

L-strand synthesis during mtDNA replication initiates two-thirds of the way around the genome from the region of H-strand synthesis²⁴. In mouse cell mitochondria the DNA sequence immediately surrounding the L-strand origin is a simple inverted repeat that may form a hairpin loop structure when the L-strand origin is exposed by H-strand displacement synthesis during DNA replication¹². An analogous and highly homologous presumptive L-strand origin exists in the human mtDNA sequence (nucleotides 5,730–5,763) within a cluster of five tRNA genes. Interestingly, the differences between the human and mouse inverted repeats occur symmetrically, so that if secondary structure did exist, full base-pairing in the stem region would be maintained.

Ribosomal RNA genes

Eperon *et al.*¹⁶ were able to align the DNA sequence with the sequences of the 5' ends^{15,25} of the 12S and 16S rRNAs and to show that there were no noncoding bases between the tRNA^{Phe} gene and the 12S rRNA gene, and between the tRNA^{Val} gene

Fig. 1 The DNA sequence of human mitochondria (pages 459–461). The sequence of the L strand is numbered arbitrarily from the *Mbo*I-5/7 boundary⁵⁶ in the D-loop region. The sequence is displayed using the program TRANMT of Staden (unpublished) and shows the position of the genes for the tRNAs (boxed) and the rRNAs (underlined). The unidentified reading frames (URF 1–6) and identified protein coding genes are translated into the one-letter amino acid code (termination codons are denoted by an asterisk). The genes for cytochrome *c* oxidase subunits I–III are abbreviated COI–III and *cyt b* denotes the gene for cytochrome *b*. Which strand contains the sense sequence of the genes is denoted by → (L strand) and ← (H strand). The ends of the presumptive mRNAs transcribed from the H strand as determined by RNA sequence analysis^{17,18} are also shown below the sequence. The 5' end of the nascent H-strand ('7S') DNA found in the D-loop is at nucleotide 191 (ref. 10). The origin of L-strand synthesis during DNA replication¹² is indicated by overlining of the possible base-pairing regions. The DNA sequence was derived mainly from a single human placenta mtDNA preparation⁵⁶ but some regions were determined on HeLa cell mtDNA. Restriction enzyme fragments of placental mtDNA were cloned in pBR322⁵⁶. Single-stranded template DNA was prepared by the exonuclease III procedure⁵⁷ and by cloning in bacteriophage M13 (refs 58–61). The DNA sequence was determined by the chain termination method of Sanger *et al.*^{62,63}. The sequence was analysed using the computer programs of Staden (refs 31, 55, 64 and unpublished). Nucleotides 10, 934–5, 14,272 and 14,365 were ambiguous and their identity assumed to be the same as in the bovine mtDNA sequence (S.A., M.H.L.B., A.R.C., I.C.E., F.S., I.G.Y., unpublished). The base composition of the L strand is 24.7% T, 31.2% C, 30.9% A and 13.1% G.

Figure 1

Figure 1

Figure 1

and the 16S rRNA gene. However, the 3' ends of the rRNA genes could only be predicted to be very close to the 5' ends of the flanking tRNA^{Val} and tRNA^{Leu} genes. It has since been shown that the mouse small subunit rRNA gene abuts the 3' tRNA^{Val} gene^{26,27} and alignment of a hamster large subunit rRNA sequence with the murine gene sequence suggests that there are also no noncoding bases between the large subunit rRNA gene and the 3' tRNA^{Leu} gene²⁸. Thus, the 12S rRNA and 16S rRNA and the flanking tRNAs in a primary transcript could be released by cleavage precisely at the 5' and 3' ends of the tRNAs without the need for further processing.

The high concentration of nascent transcripts from this region of the genome has led to the suggestion that there is a transcription attenuator in this region²⁰. This is supported by the observation that the hamster large subunit rRNA ends and is polyadenylated at any of four nucleotides within the last five nucleotides of the gene²⁸, which contrasts with the precise termini of the 12S rRNA and mRNAs^{29,30} which are presumed to be generated by processing of a primary transcript. It is possible that the 12S rRNA is also adenylated at the 3' terminus after transcription and processing: a single addition has been proposed for the hamster small subunit rRNA by comparison with the murine gene sequence³⁰.

The sequences of the rRNA genes were interpreted to provide support for a model in which mt ribosomes did not have sequence-dependent signals for recognition of the correct initiation codon but rather initiated at the first initiation codon in the mRNA¹⁶. This is consistent with the known 5'-end sequences of the mRNAs¹⁸ although not with the observation of single transcripts covering the URF A6L/ATPase 6 and URF 4L/URF 4 reading frames (Fig. 2) if the expected proteins are expressed.

The tRNA genes

Twenty-two tRNA genes have been identified in the human mtDNA sequence either by visual inspection or using the program TRNA³¹. Equivalent genes have been located in the bovine mtDNA sequence and most of these have been confirmed by direct sequencing of bovine mitochondrial tRNAs (B. A. Roe, E. Y. Chen, P. W. Armstrong and J. F. H. Wong, unpublished). We have been unable to substantiate a previous report⁸ which tentatively identified a gene for tRNA^{Met}. Apart from the tRNA^{Met}, these 22 tRNAs are sufficient to read all codons using a mechanism unique to mitochondrial systems⁷⁻⁹. No mammalian mt tRNAs have been shown to be imported from the cytoplasm (ref. 32 and B. A. Roe and E. Y. Chen, unpublished results). It had previously been assumed that the minimum number of tRNAs required to read all codons would be 32 for the 'universal' genetic code using G:U or I:A/C/U wobble³³. In human mitochondria the tRNAs for the two-codon families, that is, those genetic code boxes with two codons for one amino acid, have G:U wobble anticodons. However, only one tRNA is found for each of the four-codon families⁸ (see Table 1). These tRNAs have a U in the first position of the anticodon although each must read all four codons in its respective family. This is probably accomplished by U:N wobble⁸, although a two-out-of-three mechanism might operate³⁴. Although the modification pattern of the U in the first position of the anticodon of mammalian mt tRNAs is now known, it is likely that a similar situation exists to that found in *Neurospora* mitochondria⁷, whereby the tRNAs for the four-codon families have an unmodified U, but when the U is required for reading the two-codon families it is modified. This modification presumably prevents such tRNAs from reading codons ending in U or C.

Two species of mammalian mt methionyl tRNAs have been identified, a tRNA^{Met} and a tRNA^{Met} (refs 32, 35). Hybridization of these tRNAs to mtDNA showed partial additivity, indicating the existence of two separate genes³². In the DNA sequences we have only been able to identify one tRNA^{Met} gene, presumably coding for the initiator tRNA, based on its anticodon sequence CAT and the close homology of its anticodon arm with other initiator tRNAs (see ref. 36). The tRNA anti-

codon sequence CAU should normally be specific for AUG but as discussed below we believe that AUA and possibly AUU are also initiation codons in mammalian mitochondria. To recognize AUA (and AUU?) as well as AUG, the C in the first position of the anticodon would probably have to be modified. The AUA-specific tRNA^{Met} of *Escherichia coli* and of bacteriophage T4 have modified C residues in the first position of the anticodon^{37,38}, and hence represent examples of specific recognition of AUA by a tRNA with a CAU anticodon. Although potential tRNA^{Met}-like structures are found in the human and bovine sequences, none of these is particularly convincing nor are they conserved in the corresponding sequence. Also, extensive sequence analysis of the bovine mt tRNAs has not revealed any candidate for a tRNA^{Met} (B. A. Roe, E. Y. Chen, P. W. Armstrong and J. F. H. Wong, personal communication). If the gene exists in the mt genome it may have an unusual structure that is preventing its detection, for example, like that of tRNA^{Ser}_{AGU/C} which completely lacks the D arm³⁹. The other possibility is that one gene can give rise to both a tRNA^{Met} and a tRNA^{Met} by differential modification, although the hybridization data of Aujame and Freeman³² suggest otherwise. We are at present trying to clarify this problem by hybridization of labelled methionyl tRNA to restriction fragments of mtDNA.

The sequences of the mammalian mt tRNAs are unusual in that all, except tRNA^{Leu}_{UUR}, lack some or all of the following features found in other tRNAs: (1) the universal sequence G-T-ψ-C-R-A, (2) the constant seven-base length of the 'TψC' loop which in mammalian mt tRNAs varies between three and nine bases, and (3) the constant bases A₁₄, G₁₅ and G₁₈G₁₉ and the connections with U₈ and U₄₈ (yeast tRNA^{Phe} numbering system, see ref. 40). Thus, the mt tRNAs are apparently stabilized by fewer tertiary interactions. The most extreme case is that of tRNA^{Ser}_{AGU/C}, which lacks the D arm³⁹. Also, considering the similarity of homologous cytoplasmic tRNA species from different animals it is surprising that substantial variations are found when specific tRNAs from human and bovine mitochondria are compared. A compilation and comparison of these tRNAs will be published elsewhere. These missing or different tertiary interactions may mean that the mammalian mitochondrial tRNAs have more freedom than cytoplasmic tRNAs to evolve in certain areas, perhaps reflecting a different interaction with the ribosome. The role of the tRNAs in processing of the primary transcript is discussed below.

Table 2 Characteristics of human mt genes and comparison with bovine mt genes

Gene	Protein length	Molecular weight	% Amino acid conservation	Initiation and termination codons	
				Human	Bovine
URF1	318	35,600	75.79	ATA *	ATG *
URF2	347	38,900	62.82	ATT *	ATA *
COI	513	57,000	91.23	ATG AGA	ATG TAA
COII	227	25,500	72.69	ATG TAG	ATG TAA
URF A6L	68	7,900	51.52	ATG TAG?	ATG TAA?
ATPase 6	226	24,800	77.88	ATG *	ATG *
COIII	261	30,000	86.97	ATG *	ATG *
URF3	115	13,200	73.91	ATA *	ATA *
URF 4L	98	10,700	73.47	ATG TAA?	ATG TAA?
URF4	459	51,400	74.07	ATG *	ATG *
URF5	603	66,600	69.49	ATA TAA	ATA TAA
URF6	174	18,600	62.64	ATG AGG	ATG TAA
Cytochrome b	380	42,700	78.10	ATG *	ATG AGA

The predicted length and molecular weight of the expected products of the human mt genes and unidentified reading frames were calculated from the DNA sequence using the computer programs of Staden (ref. 55 and unpublished results). Also shown is the percentage identical amino acids conserved between the human and bovine sequences calculated using the program AACHAN (R. Staden, unpublished). The predicted initiation and termination codons of the human and bovine genes are shown; * indicates that the termination codon is created post-transcriptionally by polyadenylation (see text).

Protein coding genes

Thirteen significant reading frames have been identified in the human mtDNA sequence, of which five have been assigned to

Fig. 2 Organization of the genome. A schematic representation of the sequence shown in Fig. 1. The tRNA genes are identified by the one-letter amino acid code and their sense sequence by either $\rightarrow$ (L strand) or $\leftarrow$ (H strand). Unidentified reading frames 1–5 (URF1–5) and the identified protein genes for cytochrome *c* oxidase subunits I–III (COI–III), ATPase 6 and cytochrome *b* (cyt *b*) all have their sense sequence on the L strand; URF6, however, is H-strand coded. The number of noncoding bases between genes is given below the junctions of the genes. A minus number denotes an overlap and an asterisk indicates that there are no noncoding bases at that point and that the termination codon for the preceding gene is created in the mRNA by polyadenylation (see text). The numbered RNAs are the presumptive mRNAs transcribed from the H strand which were aligned with the DNA sequence by hybridization to restriction fragments and by sequence analysis of their 5' and 3' ends (see accompanying articles^{17,18} for a more detailed transcription map showing the positions of the L-strand transcripts and the precursors to the H-strand transcripts).

known mitochondrially synthesized proteins. Only reading frames of at least 40 amino acids conserved with at least 50% amino acid homology in the bovine sequence were considered. The gene for cytochrome *c* oxidase subunit I (COI) was identified from an N-terminal amino acid sequence of the bovine protein (J. E. Walker, personal communication) and confirmed by comparison with the yeast mt COI gene. COII was identified from the complete amino acid sequence of the bovine protein⁴¹ and COIII by homology with the yeast gene⁴² and by an N-terminal sequence of the bovine protein (G. Buse, personal communication). The genes for ATPase 6 and cytochrome *b* were identified by homology with the corresponding yeast genes^{43,44} and also by amino acid sequences of bovine cytochrome *b* (W. Machleidt, personal communication). We have found no homology between the bovine amino acid sequence of ATPase 9 (E. Wachter, personal communication) and any of the reading frames, so that, as in *Neurospora*⁴⁵, this protein must be nuclear coded; in yeast it is mitochondrially coded^{46,47}.

In regions representing identified genes the respective human and bovine sequences are highly homologous. As shown in Table 2, there is ~80% amino acid conservation, which is 5% higher than the nucleotide conservation, reflecting the degeneracy of the genetic code. Over half the codons for the conserved amino acids are different in the third (degenerate) position or, in the case of the leucine codons UUR and CUN, in the first and third positions.

We have found eight unidentified reading frames (URFs) that are conserved in human and bovine mtDNA. On average, these show ~70% nucleotide and amino acid conservation (Table 2), again with approximately half of the conserved amino acids having changed codons. This type of homology is unlikely to have occurred by chance: for example, if the reading frames are compared out of phase in the +1 and +2 frames, the amino acid homology, including all the termination codons, is 35.4% and the percentage of conserved amino acids with changed codons drops to 4.5%. Therefore, we believe that most, if not all, of these reading frames represent genes for mammalian mitochondrial proteins. Further evidence in support of this is provided by the mapping and sequence analysis of the polyadenylated presumptive mRNAs reported in the accompanying articles^{17,18}. These RNAs correspond exactly to the reading frames of URF1, URF2, COI, COII, URF A6L and ATPase 6, COIII, URF3, URF 4L and URF4, URF5 and the antisense of URF6, and cytochrome *b* as shown in Figs 1 and 2. In addition, there are large L-strand transcripts covering the H-strand-coded URF6, and the number and sizes of these reading frames are in fairly good agreement with the band pattern obtained by

gel electrophoresis of HeLa cell mt proteins produced in the presence of emetine, an inhibitor of cytoplasmic protein synthesis (J. E. Walker, personal communication).

Two of the H-strand transcripts contain more than one reading frame, RNA14 (URF A6L and ATPase 6) and RNA7 (URF 4L and URF4). These present an anomaly and it is not known whether the reading frames are separated by a further processing event of these RNAs. The same organization is found in bovine mtDNA, making it unlikely that the breaks in the reading frames are due to sequence errors. A possible explanation is that these frames contain short intervening sequences which, when excised, leave only a single reading frame. However, using nuclease S₁ protein experiments, Ojala *et al.*⁴⁸ found no evidence for intervening sequences in the mtDNA regions coding for the polyadenylated RNAs.

Initiation codons

Although all the identified genes (except ATPase 6) and some of the URFs have an AUG initiation codon within the first six bases of their mRNA start, others do not. The first ATG in bovine URF2 is 320 codons downstream from the RNA start in a reading frame of 347 codons. Also, in human and bovine URF3 the first AUG is, respectively, 89 and 87 codons downstream in a reading frame of 115 codons. Ignoring the cases of ATPase 6 and URF4, which are the second reading frames in their presumptive mRNAs, and also the case of human URF2, which is discussed separately below, all reading frames that do not have an AUG near the 5' end of the RNAs have an AUA in an equivalent position. Thus, if these reading frames are translated completely, as their homology suggests they are, AUA must function as an initiation codon as well as AUG. AUA has already been shown to code for internal methionine as well as AUG^{2,3}. In the case of human URF2 there is an AUU in the same position as the AUA in bovine URF2. Thus, to translate completely this reading frame we must argue that, like AUA, AUU can also be an initiation codon in mitochondrial genes.

Termination of translation

Over half of the presumptive mRNAs do not have UAA or UAG termination codons at the end of the reading frame (Table 2). In three cases, human COI and URF6 and bovine cytochrome *b*, termination probably occurs at AGA and AGG codons. These have been predicted to be termination codons and not arginine codons as in the universal genetic code⁸. This is based on the observation that only CGN arginine codons are used in all the reading frames, and AGA and AGG are only found at the ends of reading frames at the junction with the next

Distinctive features of the 5'-terminal sequences of the human mitochondrial mRNAs

Julio Montoya, Deanna Ojala & Giuseppe Attardi

Division of Biology, California Institute of Technology, Pasadena, California 91125, USA

The 5'-end proximal sequences of all the putative mRNAs coded for by the heavy strand of HeLa cell mitochondrial DNA have been determined and aligned with the DNA sequence. All these mRNAs start directly at, or very near to, an AUG or AUA triplet, with the exception of one which starts at an AUU. The available evidence indicates that the terminal or subterminal AUGs and AUAs, and possibly also the terminal AUU, are initiator codons for the corresponding polypeptides. In most cases, the individual mRNA coding sequences are flanked on their 5' side by a tRNA gene, without any intervening nucleotide.

RECENT sequence analysis of human mitochondrial DNA (mtDNA) has revealed an extremely high degree of packing of genetic information in this DNA (ref. 1 and accompanying paper (ref. 26)). In agreement with these observations, a detailed transcription mapping study of HeLa cell mtDNA by the S_1 protection technique has shown that the sequences of the heavy (H) strand are almost completely saturated by the rRNAs, poly(A)-containing RNAs and tRNAs coded for by this strand^{2,3}. A particularly intriguing feature of the human mitochondrial gene organization is the frequent juxtaposition, or close proximity, of the individual protein-coding sequences, on their 5' side, with a tRNA gene or another reading frame. Thus, the gene for subunit II of cytochrome c oxidase (COII) has been shown to be immediately contiguous to a tRNA^{Asp} gene without any intervening nucleotide⁴. This unusual gene organization has raised the question of whether these putative mitochondrial mRNAs have, as all eukaryotic mRNA so far analysed^{5,6}, a 5' non-coding stretch, which may thus overlap the contiguous tRNA gene or reading frame, or whether they lack completely a leader sequence on their 5' side.

As a first approach to this question, the 5'-end proximal region of the putative COII mRNA has recently been sequenced and the sequence thus determined, aligned with the COII gene sequence⁷. The results clearly showed that the 5' end of the COII mRNA corresponds precisely with the first nucleotide of the COII coding sequence. These experiments left open the question of whether the complete lack of 5' non-coding nucleotides is a general feature of human mitochondrial mRNAs, reflecting stringent constraints in the initiation of mitochondrial protein synthesis or specific rules of RNA processing, or whether, on the contrary, the position of the initiator codon relative to the 5' end may vary in different mRNAs, possibly depending on the position of the adjacent tRNA gene or reading frame. We report here information bearing on these questions, obtained by sequencing a 5'-end proximal segment of all the H strand-coded, polysome-associated, poly(A)-containing RNAs, which are

presumably specific mRNAs, and by aligning the RNA sequences with the mtDNA sequence.

Isolation and 5'-end labelling of mitochondrial mRNAs

To isolate HeLa cell mitochondrial poly(A)-containing RNAs in adequate amounts for sequencing analysis, the micrococcal nuclease procedure for the purification of mitochondrial RNA⁸ was scaled up as previously described⁷. Figure 1a shows the electrophoretic pattern in a 1.4% agarose-CH₃HgOH slab gel, after ethidium bromide staining, of a large-scale preparation of mitochondrial oligo(dT)-bound RNA from micrococcal nuclease-treated organelles (from ~30 g of cells). One clearly recognizes the characteristic set of components previously

Table 1 5'-Terminal nucleotide analysis of *in vitro* labelled mitochondrial poly(A)-containing RNA species

Poly(A)-containing RNA species	% Of total ³² P radioactivity*			
	AMP	CMP	GMP	UMP
5	52.5	8.1	27.6	11.7
7	43.8	2.1	7.8	47.1
9	12.4	0.9	2.0	4.5
11	81.1	3.0	10.2	5.5
12	78.9	2.3	12.7	5.9
13	81.4	2.4	10.0	6.0
14	91.0	3.1	2.2	3.5
15	95.9	0.3	1.6	2.1
17	73.7	2.5	6.4	17.2

The 5'-terminal nucleotide was determined by exhaustive digestion of the *in vitro* labelled RNAs with nuclease P₁ (ref. 12, Calbiochem) and fractionation of the products on polyethyleneimine impregnated-cellulose TLC plates, as previously described⁸.

* The values refer to the radioactivity which migrated from the origin. The % of the input radioactivity recovered from the origin varied between 0.1 and 5%.

Fig. 1 Isolation and 5'-end labelling of mitochondrial poly(A)-containing RNA species. Lane *a*, electrophoretic pattern after ethidium bromide staining of the oligo(dT)-bound mitochondrial RNA fraction from 30 g of HeLa cells run through a 1.4% agarose-CH₃HgOH slab gel. Lanes *b* and *c*, RNA species 13 was eluted from several gel tracks similar to those shown in lane *a*, treated with RNase-free DNase and re-run on a gel in the same conditions (*b*), then eluted again, labelled at its 5' end with [γ -³²P]ATP and polynucleotide kinase after bacterial alkaline phosphatase treatment and re-run (*c*). Lanes *d* and *e*, re-run of RNA species 14 plus 15 (*d*) or 7 plus 9 (*e*) on 2% agarose-CH₃HgOH gels after elution from the gel track shown in lane *a* and treatment with DNase. Large-scale preparation of mitochondrial RNA by the micrococcal nuclease procedure^{7,8}, subsequent isolation and fractionation by 1.4% agarose-CH₃HgOH slab gel electrophoresis of the oligo(dT)-cellulose-bound RNA, elution, DNase treatment and re-run on agarose-CH₃HgOH slab gels of the individual components⁷, and 5' end labelling of the purified RNA species⁸ were as previously reported.

detected in ³²P-labelled preparations from HeLa cells⁹, with the exception of RNA species 1, which is extremely short-lived and present in mitochondria in very small amounts^{10,11}. Because of their relative abundance, their enrichment in partially purified polysomal structures⁹ and their relatively long half life^{10,11}, RNA species 5, 7, 9 and 11–17 in this set are probably specific mitochondrial mRNAs. Correlation of RNA sequence data, or of reading frames in mtDNA, with protein sequence data and with genetically characterized yeast gene sequences strongly supports the mRNA nature of several of these species^{1,2}. However, no direct *in vitro* demonstration of the messenger activity of these RNAs is available yet. Each of the putative mRNAs was eluted from the gel, treated with RNase-free DNase (to eliminate any contaminating DNA fragments deriving from the micrococcal nuclease treatment of the crude mitochondrial fraction) and re-run on a gel in the same conditions. As shown in Fig. 1*b* for RNA 13, a sharp band was observed at the expected position, and the RNA in this band was eluted. RNAs 7 and 9, and also RNAs 14 and 15, which were not separated from each other in the first electrophoretic run, could be resolved in a re-run on a 2% agarose-CH₃HgOH gel (Fig. 1*d*, *e*). Material purified as described above, from 40–250 g of cells, depending on the RNA species, was finally labelled at its 5' end with [γ -³²P]ATP and polynucleotide kinase after dephos-

phorylation with bacterial alkaline phosphatase, re-run on a CH₃HgOH-agarose gel (Fig. 1*c*) and eluted for the sequencing reactions.

RNA sequence analysis

The 5' termini of the isolated *in vitro* labelled RNA species were characterized first. As shown in Table 1, the distribution of radioactivity among the 5' mononucleotides indicated the adequate degree of purity of all the RNA species, with the exception of RNAs 5 and 7. RNA 5, which was the least abundant RNA species analysed, had slightly more than half of its radioactivity associated with pA, whereas RNA 7 seemed to consist of two components approximately equal in amount, one terminating in pA and the other in pU.

Sequencing of the 5' end proximal segments of the poly(A)-containing RNAs was performed by the methods of Donis-Keller *et al.*¹³ and Simoncsits *et al.*¹⁴, using cleavage of the RNAs by RNases T₁ (G-specific), A (C+U-specific) and U₂ (A-specific), followed by electrophoresis on polyacrylamide/urea gels⁸. The essential features of these RNA sequencing methods, which had been previously reported^{7,8,13,14}, were also observed here (Figs 2, 3, 4). RNases T₁ and U₂ were found to cleave regularly and exclusively after G and A, although with varying efficiency, probably depending on the surrounding sequence. RNase A cleaved exclusively after pyrimidines, but, as described previously, failed to cleave after some, especially when these were part of pyrimidine stretches. Accordingly, the absence of a band in any given position, after digestion with RNase A or U₂ or T₁, was tentatively interpreted as reflecting the presence at that position of a pyrimidine if the data indicated that this putative pyrimidine was part of a stretch of pyrimidines (two or more); in such a situation, the slowest moving among the pyrimidine-terminated oligonucleotides corresponding to the pyrimidine stretch was always clearly visible, with one or more of the other products being sometimes visible as fainter bands.

In most cases, a single band was observed at any given ladder position in the gel track, supporting the idea that a predominant RNA species was being analysed. In some cases, however, a definitely weaker band was observed at the same position as the predominant band, and disregarded as a contaminant (these weaker bands were often also present in the untreated RNA control). In a few cases, no band was seen in any of the lanes at a position corresponding to a ladder step, or two bands of comparable intensity were observed at the same position; in these cases, no conclusive identification was made.

Interpretation of the results was complicated by the presence of extra bands in the gel pattern, especially in the region corresponding to the smaller oligonucleotides. These extra bands were in general less strong than the *bona fide* specific RNase cleavage products. Because of this and because they did not correspond with bands visible in the ladder or corresponded with obviously abnormal steps of the ladder, these extra bands could usually be recognized as spurious. The nature of these extra bands is not clear. They may be due to the presence during the 5'-end-labelling reaction of contaminating RNA species or DNA fragments (deriving from DNA degradation during the DNase treatment step) in the RNA preparation, or they could reflect the formation, during the enzymatic or chemical cleavage of the RNA, of oligonucleotides with different phosphate end-groups (2', 3'-cyclic phosphate, 2' and 3' phosphate). The latter explanation seems the most likely to account for the fact that, in some sequencing analyses (RNAs 5, 7 and 17), both the specific RNase cleavage products and the chemical cleavage products gave doublets instead of single bands.

In each experiment, an untreated RNA sample was run in parallel with the RNase or chemically treated samples. Usually this control ('-Enz') did not show bands or exhibited them only in the region of the larger oligonucleotides.

The interpretation of the sequence of RNA 7 (Fig. 4) offered some difficulties because of the repetition of each band at the next position in the ladder. A similar observation had been made

Fig. 2 Sequencing gels of mitochondrial poly(A)-containing RNA species 13, 12 and 9. *a, b*, RNA 13, 25% polyacrylamide/urea gel. Shown at the top of the gel are the cleavage specificities: RNase A (C+U), alkaline ladder (L_A), RNase U₂ (A), RNase T₁ (G) and RNA incubated without enzyme (-Enz). Y indicates a pyrimidine band. *c, d*, RNA 12, digested and analysed as indicated for RNA 13. The two left lanes in *c* show the digests obtained with decreasing amounts of RNase A. L_F indicates a formamide ladder. The horizontal ticks without a letter designation indicate ladder positions for which no nucleotide assignment has been made. *e-g*, RNA 9, digested as indicated for RNA 13 and analysed on a 25% (*e, f*) or, for the sequencing of residues from ~20 to 60, a 10% (*g*) polyacrylamide/urea gel. Details of the base-specific enzymatic cleavage reactions^{7,13,14} and the conditions of electrophoretic analysis^{7,8} are described elsewhere. In some experiments, to visualize a pyrimidine band in the first or second position of the sequence, the amount of RNase A used (per ~30 ng RNA and 3 µg yeast tRNA carrier) was increased to 20 ng.

previously for 12S rRNA⁸ and interpreted to reflect the existence of two species of 12S rRNA differing in molecular size by one nucleotide at the 5' end. With RNA 7, in agreement with the P₁ digestion data (Table 1), analysis of the sequencing gel showed that it could be interpreted as resulting from the electrophoretic separation of the products of RNase digestion of two species, one starting with AUG and the other with UG; comparison with the DNA sequence (see below) confirmed the validity of this interpretation. RNA 5 is present in HeLa cells in minute amounts, and only a partial purification could be obtained even after two electrophoretic runs through CH₃HgOH-agarose slab gels, as revealed by the P₁ digestion data (Table 1). Therefore, only partial sequence data could be obtained for this RNA species. However, we could identify with reasonable confidence the first two nucleotides (AY), the sixth (Y) and the ninth (G) (not shown).

Most mRNAs start at or very near an AUG or AUA triplet

Using the criteria described above, a stretch of 10–54 nucleotides, depending on the RNA species, could be read in the sequence of all the poly(A)-containing RNAs analysed here (except RNA 5). The sequences thus obtained are shown in Fig. 5; the corresponding DNA sequences (refs 4, 15 and 26 (accompanying paper)) are also reported to show their perfect alignment with the RNA sequences. Comparison of the RNA

and DNA sequences clearly indicates that all the AYG and AYA triplets underlined in the RNA sequences are indeed AUG and AUA codons. The partial sequence data for RNA 5 are consistent with the first triplet being an AUA. Thus, the striking results of this analysis are that, with one possible exception (RNA 12), all the putative human mitochondrial mRNAs start directly with an AUG or AUA triplet (which is a methionine codon in human mitochondria¹) or have a few nucleotides (1–3) preceding the first AUG or AUA. Sequencing data of human¹⁶ and bovine cytochrome *c* oxidase subunits I (COI) and II^{1,4} and comparison with the sequences of the yeast cytochrome *b* (A. Tzagoloff, personal communication) and cytochrome *c* oxidase subunit III (COIII)¹⁷ genes have indicated that the first AUGs of RNA 9 (COI mRNA), RNA 16 (COII mRNA), RNA 15 (COIII mRNA) and RNA 11 (cytochrome *b* mRNA) are initiator codons for the corresponding polypeptides. Thus, it seems reasonable to extrapolate from these results and interpret the 5'-proximal AUGs of the other mRNAs likewise as initiator codons. The mtDNA sequencing data suggest that AUA may function as an initiator codon in human mitochondria¹, and the data presented here support this. If the first AUA of RNA 13 is indeed the initiator codon, then, with the exception of RNA 12, all putative mitochondrial mRNAs have the initiator codon within the first six nucleotides. RNA 12 may also follow this rule. In fact, in bovine mtDNA, the first triplet of the reading frame corresponding to RNA 12 is AUA, instead of AUU as in human mtDNA; this observation sugges-

Fig. 3 Sequencing gels of mitochondrial poly(A)-containing RNA species 14, 15 and 17. *a, b*, RNA 14, 25% polyacrylamide/urea gel. *c, d*, RNA 15, digested as shown for RNA 14, and analysed on a 25% (*c*) or a 10% (*d*) polyacrylamide/urea gel. *e, f*, RNA 17, digested and analysed as described for RNA 14.

ted that AUU may function as initiator codon for the polypeptide coded for by RNA 12 (ref. 1). If the 5'-end heterogeneity observed in RNA 7 is an *in vivo* phenomenon, and not a consequence of degradation during the preparation and *in vitro* labelling of the RNA, and if the molecules starting with UG also function as mRNAs, the first initiator codon which could be used in these molecules would be the AUA occurring 14-nucleotides downstream from the 5' end.

How do ribosomes attach to mitochondrial mRNAs?

The finding that most mitochondrial mRNAs either start directly at the initiator codon or have only a few nucleotides (1–8) preceding this codon poses interesting questions concerning the mechanism whereby mitochondrial ribosomes attach themselves to these messengers. Both in eukaryotic and prokaryotic mRNAs, there is a stretch of variable length preceding the initiator codon^{5,6}. In prokaryotic mRNAs there is good evidence that this stretch contains a ribosome-binding site, which includes a properly positioned sequence complementary to the 3' end of 16S rRNA^{18,19}. A single exception to this rule is that of the λ repressor mRNA involved in repressor maintenance, which starts directly at the translation initiator codon²⁰. In this case, the low efficiency of translation of the mRNA was attributed to the lack of a strong ribosome-binding site. The observation that, in the 5' non-coding region of some eukaryotic mRNAs, there is considerable complementarity with a purine-

rich sequence near the 3' end of 18S rRNA⁵ has suggested that specific mRNA-rRNA base pairing may also help the positioning of eukaryotic ribosomes on the mRNAs; however, the variability in the position of the pyrimidine-rich sequence within the mRNA molecules and even the lack of these sequences in some mRNAs questions the generality of this mechanism⁶.

Sequencing analysis of a variety of eukaryotic (cellular and viral) mRNAs has shown that in most, if not all these mRNAs, translation starts at the AUG closest to the 5' end, apparently independently of the length of the 5' non-coding region (varying in the known cases between 11 and over 200 nucleotides) and of its nucleotide sequence^{6,21}. No minimum distance between the initiator codon and 5' end of the mRNA, which would allow proper initiation, has yet been defined for cellular or viral mRNAs; however, in the case of Sindbis virus RNA, there is evidence suggesting that the AUG immediately adjacent to the cap²² is not used for initiation⁶; this would imply that cytoplasmic ribosomes cannot recognize an initiator codon in such a location. To explain why initiation of translation is limited to the most 5'-proximal AUG, a 'scanning' mechanism has been proposed⁶, whereby a 40S ribosomal subunit would attach initially to the 5' end of an RNA chain and subsequently migrate towards the interior of the RNA, stopping when the first AUG is encountered; at this point the 60S subunit would join and translation start. In this model, the cap structure would enhance the binding of the 40S subunits to the 5' end of the mRNA, but would not be required. It is interesting that HeLa cell, and in

Fig. 5 The sequences of the 5'-end proximal regions of the mitochondrial poly(A)-containing RNAs determined in the present work are shown, aligned with the corresponding mtDNA sequences. A 3'-proximal segment of the sequence of the tRNA genes lying on the 5' side of most of the poly(A)-containing RNA coding stretches is also shown. Y indicates a pyrimidine (the parentheses denote a tentative identification, as explained in the text), a dash (—), an unidentified base; at position 38 in the RNA 11 sequence two possible assignments are indicated.

general, presumably mammalian, mitochondrial mRNAs are not capped²³.

The terminal or subterminal position of the initiator codon in human mitochondrial mRNAs may eliminate the need for a scanning process, at least an extensive one. A plausible mechanism would involve attachment of the ribosome at or near the 5' end of the mRNA with recognition of the initiator codon either directly or after a fine adjustment. The secondary structure of mitochondrial mRNAs may be such that it would exclude all internal sites containing AUG or AUA codons, exposing only the terminal or subterminal one. It is also conceivable that the special features of mammalian mitochondrial ribosomes or some initiation factor would make the ribosomes suitable for recognizing the terminal or subterminal initiator codons. Analysis of the potential secondary structures of human mitochondrial mRNAs and binding studies with mitochondrial or other ribosomes should elucidate the mechanisms operating in the initiation of translation in human mitochondria.

The 5' ends of most mRNA coding sequences are immediately adjacent to tRNA genes

The complete absence or minimal length of the 5' non-coding stretch in human mitochondrial mRNAs may represent the vestige of a primitive organization, or may reflect, with other traits (for example, the relatively small size of the rRNA and tRNA species), an evolutionary trend to simplicity and economy

of the mitochondrial genome²⁴. In any case, the degree of proximity of the initiator codon to the 5' end of the mitochondrial mRNAs seems to be dictated primarily by the features of gene organization of this genome, in particular, by the positions of the tRNA genes. In fact, whatever the location of the initiator codon relative to the 5' end of the mitochondrial mRNAs, the data presented here (Fig. 5) suggest that whenever a tRNA gene exists on the 5' side of the mRNA coding sequence, the latter starts immediately after the tRNA gene. This observation confirms and refines the results of a recent detailed transcription analysis of HeLa cell mtDNA³. These mapping and sequencing data strongly support the idea that the tRNA sequences represent the recognition signals for a putative processing enzyme which, by precise endonucleolytic cleavages, would release the 5' ends of the mature mRNAs^{2,3}. As will be discussed elsewhere²⁵, recent experimental evidence indicates that the tRNA sequences may perform a similar function in the processing steps which release the 3' ends of the human mitochondrial mRNAs. These striking features of the organization of the human mitochondrial genome underlie the crucial part that the tRNA sequences probably play in mitochondrial RNA processing in human cells^{2,3}.

This work was supported by NIH grants GM-11726 and GM-07616. We thank Drs F. Sanger and B. Barrell for communicating the human mtDNA sequence before publication. The technical assistance of Ms A. Drew is gratefully acknowledged.

tRNA punctuation model of RNA processing in human mitochondria

Deanna Ojala, Julio Montoya & Giuseppe Attardi

Division of Biology, California Institute of Technology, Pasadena, California 91125, USA

A 3'-end proximal segment of most of the putative mRNAs encoded in the heavy strand of HeLa cell mtDNA has been partially sequenced and aligned with the DNA sequence. In all cases, the 3'-end nucleotide of the individual mRNA coding sequences has been found to be immediately contiguous to a tRNA gene or another mRNA coding sequence. These and previous results indicate that the heavy (H) strand sequences coding for the rRNA, poly(A)-containing RNA and tRNA species form a continuum extending over almost the entire length of this strand. We propose that the H strand is transcribed into a single polycistronic RNA molecule, which is processed later into mature species by precise endonucleolytic cleavages which occur, in most cases, immediately before and after a tRNA sequence.

RECENT transcription mapping analysis of HeLa cell mitochondrial DNA (mtDNA) has revealed that the H-strand sequences specifying the rRNA and poly(A)-containing RNA species (which are probably specific mRNAs or their precursors) are flanked on one side, and often on both sides, by a tRNA gene^{1,2} (Fig. 1). In agreement with these observations, the alignment with the mtDNA sequence (refs 3–5 and 37) of a 5'-end proximal sequence of all H strand-coded putative mRNAs has shown that the sequences complementary to these mRNAs are almost always immediately adjacent, without any intervening nucleotide, to a tRNA gene or an mRNA coding sequence^{6,7}.

Here, we report that each of the eight mRNAs analysed is immediately contiguous, on its 3' side, to a tRNA gene or an mRNA coding sequence. On the basis of these and previous results^{2,4,6–8}, we propose a model of H-strand gene expression which involves transcription of almost the entire length of this strand in the form of a single polycistronic RNA molecule and its subsequent processing directed by the tRNA sequences.

Isolation and 3'-end sequencing analysis of mitochondrial mRNAs

The putative mRNAs were isolated from the poly(A)-containing RNA fraction of micrococcal nuclease-treated mitochondria

Fig. 1 Transcription map of HeLa cell mtDNA. The two mtDNA strands have been linearized at the origin of replication (0). The position and identities of the tRNA genes on the H strand (●) and on the L strand (○) were sequence (refs 16 and 37). The solid and hatched bars indicate the H-strand and L-strand transcripts, respectively; numbers refer to the various poly(A)-containing RNA species according to the classification of Amalric *et al.*¹⁹. The upper and lower arrows indicate the direction of L- and H-strand transcription, respectively. kbp, Kilobase pairs.

by electrophoresis through an agarose-CH₃HgOH slab gel, elution of the individual species from the gel, treatment with RNase-free DNase and re-run of each species on a separate gel of the same type, as described elsewhere⁶.

Partial sequence analysis of the mRNAs was carried out by an adaptation of the minus sequencing method using 'phased' oligo (dT) primers and reverse transcriptase^{9,10}, as described in Fig. 2 legend. In the transcriptase reaction, labelled primers and unlabelled dNTPs¹¹ were used rather than unlabelled primers and [α -³²P]dNTPs, as in the usual procedures; in the latter approach, the probable presence of contaminating oligonucleotides resulting from the DNase treatment (which could function as primers) was expected to complicate considerably the interpretation of the results.

To determine the correct primer to be used with the RNA being investigated (and thus the identity of the nucleotide adjacent to the poly(A) tail) each of three 5'-end-labelled primers [p(dT)₈-dA, p(dT)₈-dC and p(dT)₈-dG] was tested for its ability to prime cDNA synthesis using the RNA as a template. As shown previously^{9,10}, the presence of a specific nucleotide at the 3' end of the oligo(dT) stretch ensured that only the primer molecules hybridized with the RNA in phase (that is, those base-paired with the eight most 5'-proximal residues of the poly(A) tail and the first nucleotide on the 5' side of this tail) would promote extension synthesis by the reverse transcriptase. The band pattern formed by the products of this synthesis showed a highly variable intensity of the individual bands, and was very typical and highly reproducible for each RNA, thus providing a diagnostic test of a positive result; only limited extension synthesis was observed when the two other, non-specific primers were tested with the same RNA.

The correct oligo(dT)-dN primer identified for each RNA was incubated with the corresponding RNA, dNTPs and reverse transcriptase in four incubation mixtures, each lacking one of the four dNTPs. Figure 2 shows representative results obtained with some of the various putative mRNAs analysed. In general, in each 'minus' reaction mixture, a prominent band can be observed which corresponds to a specific ladder position. This band represents the oligo(dT) primer extended by the reverse transcriptase up to the position preceding, in the cDNA sequence, the nucleotide missing from the reaction mixture. For example, in the experiment using RNA 13, the '-A' lane shows a band at ladder position 15, the '-C' lane a band at position 25, and the '-T' lane a band at position 11. Therefore, the identities of the nucleotides at positions 16, 26 and 12 in the cDNA can be interpreted as A, C and T, respectively, and those of the

corresponding nucleotides in the RNA template U, G and A. The '-G' lane shows no band above the primer, which indicates the presence of a C residue at the position in the RNA sequence corresponding to step 10 of the ladder. The other RNA species gave results similar to those obtained for RNA 13. However, in some cases, an unambiguous identification of the stop positions corresponding to all four nucleotides could not be made. In particular, RNA 12 did not produce the expected band at position 10. Recent experiments suggest that this is probably due to the melting of the short extended primer (10 nucleotides long, comprising Ts and As) from the RNA template during the chromatography step. In the case of RNA 7, the strong signal from the band of the primer (position 9) prevented the recognition of the band at position 10. In these cases, a positive identification could not be made for position 10 or 11 in the cDNA. A faint second band was observed in some cases at a position higher up than that of the first band (see the '-G' lane for RNA 12 and the '-A' lane for RNA 16). This second band was tentatively interpreted to be due to partial readthrough by the transcriptase past the first stop position (presumably because of the presence of contaminating nucleotides in the reaction mixture) and arrest at the next stop position dictated by the sequence. In some experiments, multiple prominent bands were observed in an individual lane at positions below the stop band; these generally correlated with prominent ladder bands (for example, the '-C' lane for RNA 12), and were interpreted as reflecting pauses in the transcriptase progression, as previously observed¹², and were thus disregarded.

mRNA coding sequences are immediately adjacent at their 3' end to tRNA genes or other mRNA coding sequences

The partial sequencing data determined for the 3'-end proximal segments of the putative mRNAs are shown in Fig. 3. The corresponding DNA sequences (refs 3-5 and 37) are also reported to show their alignment with the nucleotides identified in the RNAs. Our experimental data allowed unambiguous matching of the RNA and DNA sequences. The only discrepancy observed is at a residue in RNA 11 corresponding to ladder position 13, where A was found instead of G. This may reflect a sequence difference between human placenta mtDNA (used for DNA sequencing) and HeLa mtDNA; such sequence differences have been previously observed at other positions⁴. It is interesting that the base substitution mentioned above does not change the codon assignment at that position (tryptophan). It is clear from

Fig. 2 Reverse transcriptase products in reactions using 'phased' oligo(dT) primers and poly(A)-containing RNAs 13, 12, 9 and 16. Partial sequence analysis of the 3'-end proximal segment of each RNA species was done by an adaptation of the 'minus' sequencing method using 'phased' oligo(dT) primers and reverse transcriptase^{9,10}, which will be described in detail elsewhere. Briefly, the p(dT)₈-dA, p(dT)₈-dC and p(dT)₈-dG primers were 5'-end labelled with [γ -³²P]ATP (8,000 Ci mmol⁻¹) and T4 polynucleotide kinase, after dephosphorylation with bacterial alkaline phosphatase⁸, then run on a

15% polyacrylamide slab gel in Tris-borate-EDTA. After autoradiography, the band corresponding to nonanucleotides in each lane, which contained most of the radioactivity, was eluted; the final specific activity of the labelled primers was $5-10 \times 10^7$ c.p.m. μg^{-1} . To determine the nucleotide adjacent to the poly(A) tail in the RNAs to be analysed, each RNA species (0.05–0.10 pmol) was mixed at 4 °C with a 100-fold molar excess of each of the 5'-end-labelled primers and 50 mM of each of the four dNTPs in 20 μl of 0.05 M Tris, pH 8.0 (25 °C), 0.05 M KCl, 0.005 M MgCl₂ and 0.01 M dithiothreitol. After addition of AMV reverse transcriptase (4 U), the reaction mixtures were incubated for 3 min at 39 °C. In some experiments, to facilitate the hybridization of the primer with the RNA, the mixtures were incubated for 5 min at 75 °C and then cooled for 15 min at 4 °C, before addition of the reverse transcriptase; however, no difference in results was observed. After stopping the reaction by cooling and addition of 0.01 M EDTA, the reaction products were precipitated with ethanol in the presence of 0.3 M NaCl and carrier yeast tRNA, the precipitates washed with ethanol, dissolved in 0.001 M Tris-EDTA, mixed with an equal volume of 10 M urea, heated for 2 min at 90 °C, then run on a thin (0.5 mm) 10% polyacrylamide/7 M urea sequencing gel for 3.5 h at 1,000 V. The correct oligo(dT) primer for each RNA, identified from the electrophoretic pattern of the products (see text: p(dT)₈-dA for RNAs 13 and 12, p(dT)₈-dG for RNAs 9 and 16), was incubated as described above with the corresponding RNA, dNTPs and reverse transcriptase in four reaction mixtures, each lacking one of the four dNTPs. In addition, a 'ladder' (L) reaction was performed in which all the four dNTPs were present. After stopping the reaction by quick cooling and addition of EDTA, excess primer was separated from the RNA-DNA hybrid by passage through a Sephadex G50 column equilibrated with 0.3 M NaCl, 0.01 M Tris, pH 7.4, in the presence of yeast tRNA carrier. The material in the void volume was ethanol-precipitated and then run on a 10% polyacrylamide/7 M urea sequencing gel. Arrows indicate the bands interpreted as corresponding to stop positions in the reverse transcriptase reaction. The numbering of the ladder steps indicates the molecular length (number of nucleotides) of the extended primers, starting from the 5'-end nucleotide.

Fig. 3 that the most 3'-proximal nucleotide identified directly in the RNA sequence either corresponds in the DNA to a residue immediately adjacent to the 5' end of a tRNA gene (RNAs 12, 16, 15, 7 and 11), or is separated from it by one to three As (RNAs 13 and 9). The most 3'-end proximal nucleotide identified in RNA 14 corresponds in the DNA to a residue separated by one A from the initiator codon (AUG) of the flanking RNA 15 coding sequence. Our experimental approach to the 3'-end sequence analysis did not allow discrimination between any 3'-terminal A encoded in the DNA and the As of the poly(A) tail. However, as in most of the mRNAs analysed, the most 3'-proximal nucleotide different from A corresponds to a nucleotide in the DNA immediately contiguous to a tRNA gene, it seems reasonable to extrapolate from these results and to assume that, in the other mRNA also, where one to three As separate this nucleotide from a tRNA gene or an mRNA coding sequence, these As are similarly transcribed from the DNA.

Comparison of the 3'-end proximal sequence of the small mitochondrial rRNA from hamster cells¹³ with the sequence of the corresponding segment of the human 12S rRNA gene⁴ shows a high degree of homology, with the most 3'-proximal nucleotide of the hamster RNA missing in the human mtDNA sequence which just precedes the tRNA^{Val} gene (Fig. 3). Therefore, it seems very likely that, as in mouse mtDNA¹⁴, the human 12S rRNA gene extends to the tRNA^{Val} gene, thus following the same rule described for the mRNA coding sequences. No direct information about the 3'-end proximal sequence of human 16S rRNA is available; however, comparison of the length of this RNA determined from S₁ protection data (~1,600 nucleotide)¹⁵ with the length of the interval between the tRNA^{Val} and the tRNA^{Leu} genes (1,559 nucleotides)⁴ strongly suggests that the 3'

end of the 16S rRNA corresponds to a residue in DNA immediately adjacent, or very close, to the tRNA^{Leu} gene.

In view of the exceedingly small amount of material available, no 3'-end sequence information was obtained for either RNA 5 or 17. However, the almost perfect correspondence between the molecular size of RNA 17, as estimated from S₁ protection data (340 nucleotides), and the length of the DNA sequence between tRNA^{Gly} and tRNA^{Arg} (346 nucleotides)², and the previously demonstrated juxtaposition of the tRNA^{Gly} gene with the 5' end of the RNA 17 coding sequence⁷ strongly suggest that the 3' end of the sequence specifying RNA 17 is immediately adjacent to the tRNA^{Arg} gene. Similarly, the mapping contiguity of the sequences coding for RNAs 5 and 11 (ref. 2) probably reflects their immediate juxtaposition at the nucleotide level.

Most mitochondrial mRNAs terminate with U or UA

Most of the 3'-end proximal sequences of the mitochondrial mRNAs terminate with U or UA (Fig. 3). The significance of this observation has been clarified by the analysis of the human mtDNA sequence (refs 16 and 37). It has been found that many reading frames, including those corresponding to the mRNAs mentioned above, lack a stop codon, and that, in these cases, a T or TA follows the last sense codon and immediately precedes a tRNA gene or another reading frame. This observation has led to the suggestion that poly(A) addition to the 3'-terminal U or UA of the transcripts of these reading frames may create the missing stop codon. The 3'-end proximal sequences determined here for the mitochondrial mRNAs strongly support this model for polypeptide chain termination in human mitochondria. The

reading frames corresponding to RNAs 9 and 16 have stop codons AGA and UAG, respectively^{3,5} (AGA is probably a stop codon in human mitochondria¹⁷). The observation that in these mRNAs there is a 3' noncoding stretch extending to the 5' end of the flanking tRNA gene indicates that, as in the case of the 5' terminus of the human mitochondrial mRNAs⁷, the rule dictating the possible presence and length of a 3'-end segment flanking the polypeptide coding sequence is the position of the tRNA genes in the DNA sequence.

The tRNA punctuation model of H-strand gene expression

The sequence data discussed above and in the accompanying paper⁷ and the results of previous work^{4,8} indicate that the H-strand sequences coding for the rRNAs, poly(A)-containing RNAs and tRNAs are immediately contiguous to each other, extending continuously from coordinate 2/100 to coordinate 95/100 (relative to the origin 0/100). This arrangement is consistent with a model of transcription of the H strand in the form of a single molecule which is processed by precise endonucleolytic cleavages before and after each tRNA

sequence to yield the mature products or, in some cases, processing intermediates, like the putative precursor of the rRNAs (RNA 4) and the precursor of RNA 9 (ref. 2).

Recent work has indicated a concentration of H-strand nascent transcripts in the quadrant of the mtDNA *Hpa*II map which is adjacent to the origin of replication in the direction of H-strand transcription¹⁸ (Fig. 4a). These results strongly suggest that the region of mtDNA around the origin of replication contains an initiation site for H-strand transcription—such a site may thus represent the promoter of the single transcript postulated here. Furthermore, the failure to detect any giant-size H-strand transcripts either associated with transcription complexes¹⁸ or as discrete species^{2,19}, in contrast to the occurrence of discrete giant-size L-strand transcripts, points to the possibility that the processing of the H-strand transcripts proceeds while they still reside on the mtDNA transcription complexes. These results taken together support a model in which transcription of the H strand starts near the origin of replication and proceeds uninterruptedly at least up to the distal end of the D-loop, while the growing chains are processed to yield the mature rRNAs, poly(A)-containing RNAs and tRNAs (Fig. 4b).

Hamster
small rRNA

Fig. 3 Partial sequencing data determined for the 3'-end regions of the mitochondrial poly(A)-containing RNAs are shown aligned with the corresponding DNA sequences. A 5'-proximal segment of the sequence of the adjacent tRNA genes and of the RNA 15 coding stretch is also shown. The figure also includes the 3'-end proximal sequence of the hamster small mitochondrial rRNA¹³, together with the corresponding human mtDNA sequence and a portion of the contiguous tRNA^{Val} coding sequence. Asterisks indicate the non-homologous nucleotides.

Fig. 4 Proposed model for mtDNA H-strand transcription. *a*, Distribution in the mtDNA H strand of the hybrids formed with nascent RNA chains isolated from transcription complexes (modified from ref. 18). Each tick marks the position in the *Hpa*II map (not shown) of one end of each hybrid, while the other end is arbitrarily localized at the closest, origin-proximal *Hpa*II site; long and short ticks refer to abundant and rare hybrids, respectively. *b*, Diagrammatic representation of the processing of nascent mitochondrial RNA chains in the transcription complexes: ●, tRNA gene; ○, mature tRNA.

In the processing of the primary transcripts, the secondary structure of the tRNA sequences may represent the main recognition signal, providing the punctuation in the reading of mtDNA information¹. In fact, these sequences may acquire a clover-leaf configuration while they are still a part of the nascent transcripts, and the processing enzyme(s) may recognize this structure or a portion of it. It is interesting that the *Escherichia coli* RNase P²⁰⁻²³ and a similar *in vitro* enzymatic activity from *Bombyx mori*²⁴ catalyse, in the tRNA precursors, precise endonucleolytic cleavages at the 5' terminus of the mature tRNAs, while the production of the 3' terminus of mature tRNAs in *E. coli*^{22,25} and *B. mori*²⁴ involves a 3' → 5' exonuclease activity, following an endonucleolytic event at some distance from the 3' end. There is good evidence to indicate that the RNase P recognizes some aspect of the structural conformation of the tRNA rather than the nucleotide sequence at its cleavage sites in the tRNA precursors^{26,27}. It is possible that two enzymatic activities analogous to RNase P, but with different specificities for the 5' and 3' terminus of the tRNAs, are involved in the processing of the H-strand primary transcripts in human mitochondria.

There are a few processing sites in the H-strand transcripts where no tRNA sequences have been found (see Fig. 1)—at such positions, it is conceivable that the processing enzyme(s) recognizes, on one or the other side of the cleavage point, a stem-and-loop structure resembling a portion of a tRNA configuration.

Polyadenylation occurs at endonucleolytic cleavage sites of primary transcripts

One interesting observation is that all the RNA species other than tRNAs which derive from the primary processing of the nascent H-strand transcripts are polyadenylated. This suggests that polyadenylation may be linked in some way to the process-

ing step that releases the 3' end of these RNA products from the flanking tRNA sequences, independently of the functional role of the products. This interpretation may account for the polyadenylation of the presumptive rRNA precursor^{2,28}. The small fraction of 16S rRNA which binds to oligo(dT)-cellulose^{2,19} probably represents incompletely processed 16S rRNA molecules with residual poly(A) tails. It is interesting to note that, in nuclear RNA (both cellular and viral), addition of poly(A) to the 3' ends is a rapid event which seems to precede splicing²⁹⁻³¹; furthermore, at least in most of the transcripts in adenovirus 2 and SV40 infection, the acceptor sites for polyadenylation are generated by endonucleolytic cleavages of larger primary transcripts^{29,32}.

Implications for mitochondrial RNA metabolism

A recent estimation of the steady-state amounts of the mitochondrial mature RNA species has indicated that the molar amount of 12S rRNA is about 60 times higher than that of the most abundant mRNA, RNA 16, with moderate variations in the amounts of the different H strand-coded mRNAs^{33,34}. Because the half life of the 12S rRNA is only 2-5 times longer than that of the mRNAs^{33,34} a difference in the rate of synthesis must be the main factor determining the large difference in amount between the rRNA and mRNA species. In fact, a 50-100-fold higher rate of synthesis has been estimated for 12S rRNA as compared with the mRNAs^{33,34}. Such a difference in rate of synthesis between rRNA and mRNA species could suggest the existence of more than one promoter for H-strand transcription. However, in view of the regular butt-jointing of the sequences coding for all the H-strand transcripts, a more plausible interpretation is that the H strand is in fact transcribed in the form of a single molecule, but that not all transcripts are completed before being released from the template. Premature termination of the transcripts beyond the rRNA cistrons would in fact give a larger molar yield of the rRNA species relative to that of the mRNAs or most of the tRNAs¹. Late in adenovirus 2 infection, a premature termination of transcription, which produces a four- to six-fold greater molar amount of RNA synthesized from the first 2,000 nucleotides of the transcriptional unit than from any other region, has been previously well documented³⁵, and recent evidence has strongly suggested premature termination in heterogeneous nuclear RNA synthesis³⁶. It is attractive to think that the location of the mitochondrial rRNA cistrons close to the initiation point of H-strand transcription in animal cell mtDNA, as has emerged in the course of evolution, may have been advantageous to the cell as one which gave the rRNA cistrons a transcription advantage.

This work was supported by NIH grants GM-11726 and T32 GM-07616. We thank Drs F. Sanger and B. Barrell for communicating the human mtDNA sequence before publication, and Drs D. Dubin and D. A. Clayton for sending us manuscripts in the press. The technical assistance of Ms A. Drew is acknowledged.

Activation of a cellular *onc* gene by promoter insertion in ALV-induced lymphoid leukosis

Analyses of DNA and RNA from avian leukosis virus (ALV)-induced lymphomas have provided strong evidence that, in most tumours, ALV induces neoplastic disease by activating the c-myc gene, the cellular counterpart of the transforming gene of MC29 virus. The data indicate that, as a rare event, the ALV provirus integrates adjacent to the c-myc gene and that transcription, initiating from a viral promoter, causes enhanced expression of c-myc, leading to neoplastic transformation.

RNA TUMOUR VIRUSES include acute transforming viruses (sarcoma and acute leukaemia viruses) and slow transforming viruses (for example, ALVs and murine leukaemia viruses). The mechanism by which the slow transforming viruses induce neoplastic disease has, until recently, remained obscure. These viruses differ from the acute transforming viruses in three important properties: (1) they induce macroscopic neoplasms in infected animals only after a latent period of 4–12 months, compared with 2–3 weeks for the acute viruses; (2) they do not induce morphological transformation at detectable frequency in tissue culture cells; and (3) they do not seem to contain a transforming gene.

ALVs cause B-cell lymphomas and occasionally fibrosarcomas, nephroblastomas, erythroblastosis, osteopetrosis, and anaemia. Recent evidence suggests that these viruses cause neoplastic transformation by activating a normal cellular gene(s). (1) Many ALV-induced lymphomas do not contain viral 35S and/or 21S mRNAs^{1,2} and many of the integrated proviruses in these tumours are defective^{1–3}. Thus it seems unlikely that a viral gene product is required for maintenance of neoplastic transformation. (2) The oncogenic potential of ALV seems to reside within the 3' portion of the viral genome—within ~500 nucleotides from the poly (A) tract^{4–6}—a region which does not seem to encode a viral protein⁷. (3) ALV-induced lymphomas contain proviruses integrated at one or more sites. However, at least some proviral information in each tumour is found integrated at one of a limited number of common sites^{1–3}. As proviral integration is known to occur at a large number of sites on the host chromosome, possibly at random^{8–12}, this apparent specificity of integration in lymphomas suggests that neoplastic transformation requires integration adjacent to a specific gene(s). (4) Primary and metastatic tumours are clonal^{1–3,13}. Metastases in the same bird contain similar or identical patterns of proviral integration, based on restriction analyses of cellular DNA; thus, transformation is a rare event which generally occurs only once in each animal. (5) ALV-induced lymphomas and lymphoma-derived cell lines contain new tumour-specific RNAs consisting of viral 5'-terminal sequences covalently linked to cellular sequences^{1,2}. These RNAs fall into a limited number of size classes¹. (6) The tumour-specific RNAs are expressed at moderately high levels (100–300 copies per cell)¹.

Based on certain structural features of the integrated ALV provirus, we^{1,14} and others^{2,4,6,11} have suggested a model for oncogenesis consistent with all the above observations, which we have termed oncogenesis by promoter insertion (see Fig. 1). Studies in many laboratories have shown that the integrated provirus consists of the viral structural genes flanked by sequences of ~350 nucleotides, termed long terminal repeats (LTRs)^{15–18}. The LTR contains a putative promoter sequence^{7,12,19,20}. Initiation of normal viral RNA synthesis occurs within the left LTR. Because this sequence is repeated at the right end of the provirus, initiation could also occur within

the right LTR. If the provirus integrated adjacent to a potentially oncogenic cellular gene, transcription initiated from the viral promoter could generate an RNA molecule such as those found in ALV-induced lymphomas, containing both viral and cellular sequences (see Fig. 1). The resultant enhanced expression of this cellular gene would lead to neoplastic transformation. Identification of the putative cellular gene activated by this mechanism would be strong evidence in support of this model.

Over 10 different 'transforming genes' have been identified in the genomes of acute transforming retroviruses of avian and mammalian origin^{21–26}—each of these viral *onc* (*v-onc*) genes has a normal cellular counterpart (cellular *onc*, or *c-onc*)^{24,27–34}. These normal cellular genes are presumably the progenitors of the *v-onc* genes and are generally expressed at low levels in normal, uninfected cells^{29,35–38}, although they may be expressed at higher levels during certain stages of development³⁸. As they are highly conserved in vertebrate evolution^{25,29,39}, these normal cellular genes probably have some essential role in cellular growth, differentiation and/or development.

It seemed possible that the normal cellular gene(s) activated by promoter insertion might be one of the cellular counterparts of a *v-onc* gene. Here we report our efforts to identify the putative *c-onc* gene(s) involved in ALV-induced lymphomas, using cDNA probes specific for five *v-onc* genes of avian acute

Fig. 1 Structure and transcriptional products of the integrated ALV provirus. The integrated provirus is flanked by sequences of ~350 nucleotides termed long terminal repeats (LTRs^{15–18}). The LTRs, shown greatly enlarged to emphasize structural details, are composed of sequences derived from the 5' (U5) and 3' (U3) ends of genomic RNA, and a short sequence (R) of ~20 nucleotides, present at both ends of genomic RNA. Synthesis of normal viral RNA (genomic RNA and mRNAs) initiates within the left LTR. Initiation within the right LTR would generate a molecule containing viral 5' sequences (R + U5) plus cellular information encoded in the adjacent cellular DNA. If, as shown, the provirus integrated upstream from a potentially oncogenic cellular gene (designated *c-onc*), initiation within the right LTR could cause elevated expression of the *c-onc* gene.

Fig. 2 *myc*-specific and viral 5'-specific RNAs in ALV-induced lymphomas. Poly(A)-containing RNAs (2–5 µg per lane) were glyoxylated, size-fractionated on 1% agarose gels, and transferred to aminophenylthioether paper by the procedure of Alwine *et al.*⁴³, as modified by B. Seed (personal communication). Details of this procedure have been described elsewhere¹. RNAs containing viral 5'-specific and *myc*-specific sequences were identified by hybridization to ³²P-labelled cDNA_{5'} (5') and cDNA_{myc} (m) (specific activity ~2–4 × 10⁸ c.p.m. per µg). The blot was first hybridized to cDNA_{5'} and exposed to X-ray film; it was then washed in denaturing conditions to remove the cDNA probe, and re-hybridized to cDNA_{myc}. Positions of viral 35S (8.4 kilobases) and 21S (3.5 kilobases) RNAs are indicated by open arrows; 2.5- and 2.9-kilobase *myc*-specific RNAs are indicated by closed arrows. Tissues are designated as in Tables 1 and 2. kb, Kilobase.

transforming viruses. We used three criteria to identify such a gene, based on predictions of the model for oncogenesis described above: (1) the *c-onc* gene should be expressed at elevated levels in ALV-induced lymphomas; (2) the *c-onc* sequences should be encoded in the tumour-specific RNAs, covalently linked to viral sequences; (3) proviruses in ALV-induced lymphomas should be integrated adjacent to the *c-onc* gene. Based on all three criteria, the data strongly suggest that most of the ALV-induced lymphomas studied result from activation of the *c-myc* gene, the cellular counterpart of the transforming gene of MC29 virus, by a promoter insertion mechanism.

Expression of *c-onc* genes in normal and neoplastic tissues

RNA from normal tissues and ALV-induced lymphomas was analysed by nucleic acid hybridization to cDNA probes specific for the following *v-onc* genes: *src* (Rous sarcoma virus), *erb* (avian erythroblastosis virus), *myb* (avian myeloblastosis virus), *fps* (Fujinami sarcoma virus) and *myc* (myelocytomatosis virus-29, or MC29). The cellular homologues of the five *onc* genes were expressed at low but detectable levels (1–4 copies per cell) in normal tissues from 3–4-month-old uninfected birds (Table 1). With one exception (see below), the cellular *src*, *erb*, *myb* and *fps* genes were expressed at similarly low levels in lymphomatous tissues.

In contrast, levels of *myc*-specific RNA were 30–100-fold higher in ALV-induced lymphomas (90–330 copies per cell). These data suggest that *c-myc* is the cellular gene responsible for ALV-induced neoplastic transformation in these tumours. An even higher level of *myc* RNA was found in RP9 (1,000 copies per cell), a cell line derived from an ALV-induced lymphoma. In RP9 cells, *myb*-specific RNA was also elevated, but to a much lesser extent (40 copies per cell); the significance of this is unclear.

A more extensive analysis of *myc* gene expression involving a larger number of normal tissues and ALV-induced lymphomas is shown in Table 2. Each tissue was also analysed for expression of virus-specific information by hybridization to a probe representative of the entire viral genome (cDNA_{rep}), and to a probe corresponding to the 5'-terminal 101 nucleotides of viral RNA (cDNA_{5'}); the latter would detect 5'-terminal (R+U5) sequences of RNAs initiated from either the left or the right LTR (see Fig. 1). As 5'-terminal sequences comprise only ~1% of the viral genome, the presence of viral 5' sequences alone would not be detected by cDNA_{rep}. For detection by cDNA_{rep}, an RNA molecule must contain other viral genetic information.

Six main points can be drawn from the data in Table 2: (1) 12 of 14 ALV-induced lymphomas (including the lymphoma cell line RP9) contained elevated levels of *myc* RNA (at least 80 copies per cell). One additional lymphoma (29L) contained a slightly elevated level (9 copies per cell), whereas sample 25L contained only normal levels of *myc* RNA (2 copies per cell). (2) Uninfected chicken embryo fibroblasts and bursal and muscle tissues from 3–6-month-old uninfected birds contained low levels of *myc*-specific RNA (2–5 copies per cell). (3) In infected,

but non-neoplastic tissues (5B, 6B, 19M, 23M), *myc*-specific RNA levels were similar to those in tissues from uninfected birds. Viral RNA is present at elevated levels in these tissues. Thus it is clear that viral infection and/or expression of viral genes alone is not sufficient to induce *myc* expression. (4) Viral gene expression is not necessary for maintenance of neoplastic transformation. In ~50% of the tumours, cDNA_{rep}-specific RNA was present at levels (one to six copies per cell) only slightly higher than those of the endogenous provirus *ev1*⁴⁰ in normal cells⁴¹. (Most uninfected chicken cells contain genetic information homologous to the replicative genes of RNA tumour viruses. These 'endogenous proviruses' (*ev*) segregate as defined genetic loci.) (5) In each of the samples containing low amounts of RNA homologous to cDNA_{rep} (7K, 10B, 23L, 25L, 35L, 36B, 36L), viral 5'-specific sequences were present at elevated levels. In all these tumours (except 25L, in which *myc* gene expression is not elevated) the level of 5'-specific RNA was similar to that of *myc*-specific RNA. This is consistent with the interpretation that 5' and *c-myc* sequences are present on the

Table 1 Transformation-specific RNAs in ALV-induced lymphomas

Sample no.	Tissue	RNA (copies per cell)				
		<i>src</i>	<i>fps</i>	<i>erb</i>	<i>myb</i>	<i>myc</i>
12B	Uninfected	3	1	2	3	3
31L	Uninfected	2	1	4	1	2
7K	Lymphoma	4	1	6	5	110
11B	Lymphoma	3	2	2	4	180
23L	Lymphoma	5	1	2	3	330
9B	Lymphoma	5	1	4	2	230
22L	Lymphoma	4	2	ND	5	90
RP9	Lymphoma cell line	3	1	3	40	1000

Sample designations indicate the animal number and the source of the tissue: B, bursa; L, liver; K, kidney. RP9 is a continuous cell line derived from a RAV-2-induced lymphoma (provided by Dr W. Okazaki). Lymphomas were removed from leukotic birds 4–6 months after infection with ALV. Birds were injected with 10⁶–10⁷ plaque-forming units (PFU) of virus, 2–7 days after hatching. Virus strains used in this and other experiments included Rous-associated virus-1 (RAV-1), RAV-2 and transformation-defective (td) mutants of Schmidt-Ruppin Rous sarcoma virus-A (td107A, td103 and td109). No virus strain-specific differences were observed in any of the experiments described here. Normal tissues were taken from uninfected 3–6-month-old birds. Hybridizations were performed in liquid as described elsewhere³⁵, using ~5 mg ml⁻¹ of cellular RNA. Hybrid reactions were stopped at various time intervals, corresponding to C_t/t values of ~10–10⁵ mol·s⁻¹. RNA concentrations were calculated from C_t/t values (see ref. 35), assuming that a C_t/t value of 4 × 10⁴ mol·s⁻¹ is equivalent to one copy per cell. Because of variations in the RNA content of cells from different tissues, the values shown are not precise but the error introduced is no more than a factor of 2–3, and thus does not affect any of the conclusions drawn. Radiolabelled cDNA probes correspond to the unique (putative transforming) sequences of the following acute transforming viruses^{24,27,61,62}: Rous sarcoma virus (*src* gene), Fujinami sarcoma virus (*fps*), avian erythroblastosis virus (*erb*), avian myeloblastosis virus (*myb*), and myelocytomatosis virus-29 (*myc*). Probes were prepared as previously described for cDNA_{rep} (ref. 35), except that cDNA was synthesized from purified viral RNA and reverse transcriptase, using random DNA primer⁶³. Sequences unique to each of the acute transforming viruses were selected by removing sequences common to ALV (by hybridization to a mixture of ALV RNAs from RAV-1, RAV-2, RAV-61, plus erythroblastosis-associated virus for cDNA_{erb}, and myeloblastosis-associated viruses-1 and -2 for cDNA_{myb}). The probes demonstrated no cross-homology, and did not hybridize (<2%) with any of the ALV RNAs used for their selection, or to ribosomal RNA. ND, not determined.

same RNA molecules in ALV-induced lymphomas. (6) *c-myc*-specific RNA in normal cells does not contain viral 5' sequences—the latter were undetectable (less than 0.1 copy per cell) in tissues from an ev-negative bird (37L and 37B)⁴², whereas *myc*-specific RNA was present at 2 and 5 copies per cell, respectively.

Tumour-specific RNAs have *myc*-specific sequences and viral 5' sequences

To test directly whether the *myc*-specific sequences and viral 5'-sequences are encoded on the same RNA transcript, poly(A)-containing RNA from ALV-induced lymphomas was analysed by the 'Northern' transfer technique⁴³, using cDNA_{5'} and cDNA_{myc} as probes. Previous studies showed that almost all tumours synthesize discrete new tumour-specific RNAs containing viral 5' sequences plus other information, presumably derived from the cell¹. In most tumours, the size of these RNAs was ~2.5 kilobases, although a few contained RNA of ~2.9 kilobases. None of these RNAs contained sequences detectable with cDNA_{rep}. In a few tumours, larger RNAs of 5–6 kilobases were detected with cDNA_{5'}. These RNAs also contained information detectable with cDNA_{rep}.

Six of the seven samples shown in Fig. 2 contained a single major *myc*-specific RNA. In each case, this RNA corresponded to a species detectable with cDNA_{5'}, suggesting that the *myc* sequences and viral 5' sequences are present on the same RNA transcript. As reported previously¹, these RNAs are not detected with cDNA_{rep}. In five tumours, the size of this RNA was 2.5 kilobases, whereas in a sixth (23L), it was rather heterogeneous, with a size of ~2.9 kilobases. A 2.9 kilobase RNA was also found in RP9 cells, which also contained four additional *myc*-specific RNA species, each of which corresponded to a 5'-containing RNA. The three larger of these, with sizes of 7–8.5 kilobases, were rather obscured in the cDNA_{5'}-specific analyses by the presence of normal viral 35S RNA, but were seen clearly in short exposures of the blots. The high degree of specificity of the cDNA_{myc} probe can be seen from the fact that this probe did not hybridize to the 35S viral RNA in tumour 34L, although this species is much more abundant than the 2.5-kilobase RNA detected with cDNA_{5'} and cDNA_{myc}. RP9 and 34L also contain several smaller RNAs that hybridize with cDNA_{5'} and cDNA_{rep} (ref. 1) but not with cDNA_{myc}; these RNAs are presumably aberrant viral transcripts.

myc-specific RNA was not detected in normal cells under the conditions used in these experiments (data not shown). Sheiness *et al.*⁴⁴ have identified *c-myc* RNA in uninfected cells using larger amounts of cellular RNA. These workers reported a size of 2.8 kilobases, slightly larger than that of the most frequently observed *myc*-specific RNA found in ALV-induced lymphomas.

Genetic content of tumour-specific RNAs

The data described above are consistent with the interpretation that the *myc*-specific RNAs in ALV-induced lymphomas have the structure illustrated in Fig. 1 (that is, they contain only ~100 nucleotides of virus-coded information). The failure to detect these RNAs with cDNA_{rep} (ref. 1) suggests that they contain little or no viral information other than the 5'-terminal sequences detected with cDNA_{5'}. As analysis with cDNA_{rep} does not provide a sensitive assay for possible short stretches of viral information, RNA from ALV lymphomas was tested further by liquid hybridization, using probes specific for portions of the viral genome.

The low level of normal viral mRNAs in some of the tumours allowed us to examine the genetic content of the *myc*-specific RNA in these tissues. Two tumours, 7K and 23L, in which *myc*-specific RNA was at least 50-fold more abundant than viral mRNA (Table 2), were chosen. RNA from these tumours was hybridized to cDNA_{myc} (Fig. 3, broken lines) and to probes specific for the viral *gag*, *pol*, and *env* genes, the 500 nucleotides adjacent to the poly(A) tract at the 3' end of the viral genome

(cDNA_{3'}), and cDNA_{5'} (solid lines). With both tumours, cDNA_{myc} hybridized to a plateau level of ~85%, indicating extensive homology between the *myc* probe and the *c-myc* sequences encoded in the tumour-specific RNA of ALV-induced lymphomas. A plateau value of ~90% hybridization was obtained with RNA from normal cells, when hybridization was carried out to very high *C_t* values (data not shown).

Of the virus-specific probes, only cDNA_{5'} hybridized with kinetics similar to those obtained with cDNA_{myc}. Some hybridization was obtained with the other probes at much higher *C_t* values. This could reflect the presence of small amounts of viral mRNA. However, in no case were the hybridization patterns consistent with the presence of any viral sequences, other than 5'-specific sequences, in the *myc*-specific RNA transcript. Thus we conclude that, within the limits of this assay (probably ~5% of the genetic content of each probe), no viral information other than 5' sequences is present in the *myc*-specific transcripts of tumours 7K and 23L. Hybridizations of gene-specific probes to the 'Northern' blots similarly failed to detect other viral sequences on the 2.5- and 2.9-kilobase *myc*-specific RNAs (data not shown).

ALV provirus is integrated adjacent to *c-myc* in ALV-induced lymphomas

In our previous studies¹, analysis of lymphoma DNA was performed by digestion with the restriction endonuclease *EcoRI*, which cuts at several sites within the provirus^{15,5,45}. The most useful restriction fragment generated by this digestion is the right-end 'junction fragment', which contains ~150 nucleotides of viral information, plus adjacent downstream cellular DNA. If the ALV provirus is integrated adjacent to *c-myc*, this junction

Table 2 *myc*-specific and virus-specific RNA in normal and neoplastic tissues

Sample no.	Tissue	RNA (copies per cell)		
		<i>myc</i>		<i>rep</i>
2928F	Normal (uninfected)	2	18	0.7
31L	Normal (uninfected)	2	6	0.5
12B	Normal (uninfected)	3	07	0.7
37L	Normal (uninfected)	2	<0.1*	<0.1*
37B	Normal (uninfected)	5	<0.*	<0.1*
19M	Normal (infected)	2	1,500	1,300
23M	Normal (infected)	3	1,500	1,200
5B	Normal (infected)	3	145	160
6B	Normal (infected)	2	200	280
3B	Pre-neoplastic bursa	10	7	0.4
7K	Lymphoma	110	100	2
9B	Lymphoma	230	1,300	1,100†
10B	Lymphoma	100	90	2
11B	Lymphoma	180	2,500	2,000
19L	Lymphoma	85	1,900	1,300

35L	Lymphoma	80	80	6
36B	Lymphoma	100	100	2
36L	Lymphoma	140	120	3
RP9	Lymphoma cell line	1,000	4,000	600

Sample designations are as in Table 1; F, fibroblasts (chicken embryo); L, liver; B, bursa; M, muscle; K, kidney. Tissues were taken from 3–6-month-old uninfected birds, or from leukotic infected chickens 4–6 months after infection (see Table 1 for details). RNA concentrations were determined as in Table 1. RNA was detected with cDNA_{myc}, or with virus-specific probes corresponding to 5'-terminal sequences (R+U5) of genomic RNA (cDNA_{5'}) or to the entire viral genome (cDNA_{rep}). cDNA_{5'} ('strong-stop DNA'⁶⁴) was synthesized from RAV2 as described elsewhere¹; cDNA_{rep} was synthesized from RAV-2 RNA, using random DNA primer⁶³. cDNA_{5'} detects RNA transcripts initiating either from the left or right LTR (see Fig. 1), whereas cDNA_{rep} detects only viral RNA containing substantial portions of the viral coding sequences (presumably initiating from the left LTR).

* No virus-specific RNA was detected with either cDNA_{5'} or cDNA_{rep} in conditions that would have detected 0.1 copies per cell. These samples were taken from a chicken (no. 37) which lacks endogenous proviruses⁴².

† RNA from tumour 9B hybridized with kinetics suggesting two components, with levels of 25 and 1,100 copies per cell. Other experiments demonstrated the presence in this tumour of an abundant 5.5-kilobase RNA species containing *gag* and 3' viral sequences, and portions of *pol*.

Fig. 3 Genetic content of *myc*-specific RNAs in two ALV-induced lymphomas. Total cellular RNA from tumours 7K and 23L was extracted with proteinase K-phenol-chloroform³⁵, and precipitated two or three times with 2 M LiCl to remove cellular DNA. RNA was hybridized to cDNA_{myc} (broken line) and to cDNA probes specific for different portions of the ALV genome (solid lines). The following virus-specific probes were used: ▲, cDNA_{gag}; ▼, cDNA_{pol}; ×, cDNA_{env}; ●, cDNA_{5'}; and +, cDNA_{3'}. cDNA_{pol} was prepared from RAV-0, and corresponds to the deletion in ev3 RNA⁴¹, which includes a large portion of the *pol* gene, and the 3' portion of *gag*. All other probes were prepared from RAV-2. cDNA_{gag} represents the 5' 2,500 nucleotides of genomic RNA, and overlaps somewhat with cDNA_{pol}. cDNA_{env} corresponds to the *env* deletion of Bryan strain of Rous sarcoma virus, and cDNA_{3'} corresponds to the 3' 500–600 nucleotides ('common' or 'c' region) of genomic RNA. cDNA_{5'} is described in Table 2 legend. Probes were prepared and hybridizations performed as described elsewhere^{35,41}.

fragment should contain *myc*-specific sequences, and thus be detected with both cDNA_{5'} and cDNA_{myc}.

Restriction analyses of DNA from normal tissue and from three ALV-induced lymphomas are shown in Fig. 4. In normal cells, *c-myc* sequences were contained almost entirely within a single *EcoRI* restriction fragment of ~14 kilobases, consistent with the report of Sheiness *et al.*⁴⁴. (We also found a second, minor band at ~2 kilobases which has not been further characterized.)

Lymphoma DNAs contained a new *myc*-specific restriction fragment not present in normal cells (Fig. 4). In each case, this new fragment corresponded to a junction fragment detected with cDNA_{5'}. This presumably represents integration of an ALV provirus adjacent to the *c-myc* gene. In a larger sampling of lymphomas, we found that 31 out of 37 lymphoma DNAs contained proviral information integrated adjacent to *c-myc*. The 14- (and 2-) kilobase *myc*-specific *EcoRI* fragments found in normal cells were also found in the lymphomas. This would be expected because integration presumably occurs adjacent to only one of the copies of *c-myc* present in the diploid chicken genome.

We have recently succeeded in cloning the *EcoRI* junction fragments from two ALV-induced lymphomas (B.G.N. *et al.*, unpublished results). The cloned DNAs contain both viral 5' information and *myc*-specific information, thus providing direct evidence that the viral and *c-myc* sequences are covalently linked in these tumours.

Discussion

From the above data we conclude that, in almost all ALV-induced lymphomas, neoplastic transformation results from activation of the cellular gene *c-myc*. This process seems to involve integration of the provirus upstream from the *c-myc* gene, and transcriptional activation of this gene due to the insertion of the 'strong' viral promoter. The resultant RNA transcript contains both viral and *c-myc* information, and is present at levels 30–100-fold higher than that of *c-myc* RNA in normal tissues.

Integration of the provirus at a site which could activate the *c-myc* gene would presumably be a rare event, because integra-

tion is known to occur at many sites (possibly at random) in the host genome^{8–12}. Thus, this mechanism can explain, at least in part, the long latent period required for development of lymphomas in ALV-infected birds, and the failure to detect transformation in ALV-infected tissue culture cells.

We have previously observed that ALV-induced lymphomas contained proviruses integrated at a limited number of discrete sites, as judged by restriction analysis. The junction fragments of different size observed in the earlier experiments could represent ALV integrations adjacent to different cellular genes. However, our data (see Fig. 4 and ref. 46) indicate that most proviruses are integrated adjacent to the same gene, *c-myc*. Apparently, integration at several locations upstream from *c-myc* can lead to activation of this gene. Many tumours that have junction fragments of different sizes (for example, 34L and 35L) synthesize *myc*-specific RNAs of the same size (2.5 kilobases). This could be explained if the 2.5-kilobase RNAs arose by splicing events, with removal of varying lengths of intervening sequences.

It is unclear why *c-myc* should be involved in such a large percentage (~85%) of lymphomas. Over 10 transforming genes (*v-onc*), each of which has a cellular counterpart that is highly conserved in all vertebrates, have been identified in different avian and mammalian retroviruses^{21–34}—others undoubtedly exist. Although some *v-onc* genes may show tissue specificity, this alone cannot explain the preferential involvement of *c-myc* in B-cell lymphomas. MC29, an acute transforming virus which contains the *myc* gene, causes myelocytomatosis, fibrosarcomas and carcinomas in infected birds⁴⁷. No examples of B-cell lymphomas have been reported. In tissue culture, MC29 transforms both haematopoietic cells⁴⁸ and fibroblasts^{47,48}. However, other viruses (for example, AMV and AEV) also transform haematopoietic cells *in vivo* and *in vitro*²³. Nevertheless, the cellular counterparts of these *v-onc* genes are not activated by ALV in a large percentage of ALV-induced lymphomas.

Breindl *et al.*⁴⁹ have suggested that proviruses integrate preferentially into transcriptionally active regions of chromosomes. If *c-myc* is in a transcriptionally active conformation at some stage of B-cell differentiation, integration within this region might occur with a higher than random frequency. Alternatively, *c-myc* may be more readily activated by the promoter insertion mechanism, due to some structural feature(s) of this

Fig. 4 Restriction analysis of *myc*-specific and viral 5'-specific sequences in DNA from normal cells and ALV-induced lymphomas. DNA was extracted from normal brain (N) from bird no. 34, and from three ALV-induced lymphomas (designated as in Tables 1 and 2). DNA was digested with restriction endonuclease *EcoRI*, size-fractionated on agarose gels and transferred to nitrocellulose paper by the technique of Southern⁶⁵. Experimental details have been described elsewhere^{1,40}. Duplicate samples from each tissue were analysed in parallel experiments by hybridization to cDNA_{5'} (5') or cDNA_{myc} (m). Two *myc*-specific restriction fragments—a major species of 14 kilobases (open arrows) and a minor species of 2 kilobases—were detected in all DNAs from both normal and neoplastic tissues. *myc*-specific fragments of 2.9 and 2.7 kilobases (solid arrows), also detected with cDNA_{5'}, were found only in tumour DNAs. cDNA_{5'}-specific restriction fragments of the endogenous provirus ev1^{1,40} (indicated in the left lane by solid circles) were present in both normal and transformed tissues.

gene. As discussed above, integration at several sites upstream from *c-myc* can apparently result in its activation. This multiplicity of potentially 'productive' sites might increase the probability of activating this gene over other *c-onc* genes, which might only be activated by integration at a more limited number of sites.

It is possible that other *c-onc* genes are activated by promoter insertion in the ALV-induced lymphomas that do not show enhanced *myc* expression. We are currently attempting to identify the cellular gene(s) induced in these tumours.

We could find no evidence for the participation or generation of an acute transforming virus in ALV-induced lymphomas; no virus capable of transforming fibroblasts was recovered from any of the lymphomas tested (data not shown). (MC29 transforms fibroblasts in tissue culture with high efficiency.) Virus from one sample, RP9, was further tested by injection into 1–7-day-old chicks. Lymphomas appeared after a long latent period (>4 months), but no acutely developing neoplasia was observed. In addition, the structure of the *myc*-specific RNAs in lymphomas was not consistent with that of a viral genome. All known defective transforming viruses contain viral sequences at the 5' and 3' ends of their genome. Sequences at the 3' end encode recognition signals for reverse transcription of viral RNA, integration of proviral DNA and synthesis of viral mRNA. Analyses of RNA from two ALV-induced lymphomas (Fig. 3) revealed no viral 3' information. Furthermore, sequences thought to be involved in RNA packaging⁵⁰, located in the region from ~100–350 nucleotides from the 5' end⁵¹, do not seem to be present in the tumour-specific RNAs.

Cooper and Neiman⁵² using a transfection assay, recently demonstrated that DNA from ALV-induced lymphomas causes transformation of NIH/3T3 cells with high efficiency. Surprisingly, the transformants did not contain any detectable viral DNA sequences (including the LTR), nor apparently did they contain *myc*-specific sequences derived from the lymphoma DNAs. However, these investigators have recently found that the lymphomas from which the DNA was derived do contain ALV proviruses integrated adjacent to *c-myc* (G. Cooper and P. Neiman, personal communication). The transfection assay is apparently detecting another genetic change in lymphomas which may be a direct or indirect consequence of enhanced *c-myc* expression. It is possible that *c-myc* activation, and the activity detected in the transfection assay, represent different steps in a multistage process leading to neoplastic transformation.

The *onc* gene of MC29 virus^{53–55}, and those of many other acute transforming viruses⁵⁶, are expressed as *gag-onc* fusion proteins. Our data indicate that the *gag*-encoded portion of this protein is not required for the transforming activity of the *myc* gene product at least in B cells. We could detect no viral sequences other than the 5'-terminal 100 nucleotides in *myc*-specific RNA from these tumours; thus the predicted translation product of this RNA would lack *gag* sequences.

Earlier work had suggested that normal cellular information might be potentially oncogenic. Hanafusa *et al.*⁵⁷ generated acute transforming viruses (recovered avian sarcoma viruses, rASVs), by injecting transformation-defective viruses which lack most, but not all, of the *src* gene, into chickens. The rASVs have acquired most of their *src* information from the cell by recombination with *c-src*^{58–60}. These experiments suggested that *c-src*, without substantial modification, is capable of inducing cell transformation when expressed at high levels as a consequence of its incorporation into the viral genome. Recently, Oskarsson *et al.*³³ have shown that *c-mos*, the cellular counterpart of the transforming gene of Moloney murine sarcoma virus, can induce transformation of NIH/3T3 cells if the LTR is linked to cloned *c-mos* DNA. The resultant structure is similar to that found in ALV-induced lymphomas. No viral sequences other than the LTR are required for this activity (G. Vande Woude, personal communication).

It seems likely, therefore, that the role of both acute and slow RNA tumour viruses in neoplastic transformation is simply to provide a means for constitutively expressing a cellular gene that is normally expressed at low levels. These viruses accomplish this in slightly different ways. In the acute viruses, a cellular gene has been inserted into the viral genome (by recombination), where it comes under the control of the viral promoter. With slow transforming viruses such as ALV, the viral promoter is inserted into (or adjacent to) the cellular gene.

The data presented here show, for the first time, that a carcinogenic agent (ALV) acts by altering the expression of a normal cellular gene. These findings raise the interesting possibility that activation of a *c-onc* gene may be the common initiation event in neoplastic transformation by both viral and non-viral agents. Radiation and nearly all chemical carcinogens are potent mutagens—these might induce elevated expression of a *c-onc* gene by altering regulatory sequences (by point mutation or DNA modification), and/or by causing translocations that join *c-onc* coding sequences to transcriptionally active elements. The different types of cancer may reflect the particular *c-onc* gene activated, and the type of cell in which activation occurs. The availability of molecular probes for the known *onc* genes should allow screening for enhanced expression of these genes in a large number of tumours of unknown origin. Thus it should be possible to test the general validity of this model.

We thank N. Goldberg and J. Fang for technical assistance; M. Shibuya for providing *fps* probe; J.-H. Chen and S. M. Anderson for providing virus strains and RNAs; H. Hanafusa, T. Hanafusa, and L.-H. Wang for supplying some of the leukotic birds; W. Okazaki for the cell line RP9, J. Walberg for histopathological analyses; H. Hanafusa and J. Summers for critical reading of the manuscript, and G. Gasic for helpful discussions.

Although some quasistellar objects (QSOs) are known to be members of small groups of galaxies (see refs 1–3), there is no known case of a QSO in a rich cluster of galaxies⁴. Whether this has important implications for the nature of QSOs, or is simply a reflection of the difficulty of observing high-redshift clusters, is unclear. Here we report the discovery of a new QSO which provides perhaps the strongest evidence to date for quasar membership in a rich cluster.

The QSO was discovered during a programme aimed at the identification of optical counterparts of X-ray sources observed serendipitously by the Einstein Observatory. The detector used, the imaging proportional counter⁵, yields positional accuracies of the order of 1 arc min, typically restricting optical candidates for the X-ray source to only a few objects. These candidates were then each examined spectroscopically. So far we have identified more than 40 previously uncatalogued QSOs using this technique, and preliminary results on the objects as a class are reported elsewhere⁶. During X-ray observations of quasar 3C345, a serendipitous X-ray source located 8 arc min north-east of the quasar was discovered, in addition to emission from 3C345 itself. The observed flux from the new source is 3.2×10^{-13} erg cm⁻² s⁻¹ in the 0.5–4.5-keV band. This flux, which is roughly 7% of that observed from 3C345 (ref. 7), is typical of the serendipitous sources in our sample. Three separate observations during a 6-month period in 1979–80 showed no evidence for intensity variability of the new source in excess of the $\pm 20\%$ statistical uncertainty in the count rate. There was also no evidence for X-ray variability in 3C345 during this period.

Spectroscopic observations of optical candidates in the X-ray field were obtained on 16 May 1980, using the Robinson-Wampler image tube scanner⁸ at the Lick Observatory 3-m Shane reflector; the grating yields 20 Å spectral resolution in the 3,500–8,500 Å range. The X-ray source was readily identified with a previously unreported faint QSO, which we designate 1641+3998. The coordinates of the object are $\alpha(1950) = 16$ h 41 min 54.1 s, $\delta = +39^\circ 59' 17''$. Based on calibrations of the image diameter of the object on the Palomar Observatory Sky Survey⁹, we estimate the magnitude of the object at the epoch of

those plates as $B = 18.7 \pm 0.5$. Both the Sky Survey and our spectrophotometry show the QSO to be quite blue. As stressed in ref. 6, the probability of a chance coincidence of a random QSO with the X-ray source is negligible, so the identification of the quasar with the source is secure. The finding chart for the object in Fig. 1 is reproduced from a 4-m Mayall telescope plate obtained in 1973; also shown is 3C345.

The spectrum of the newly discovered QSO is of particular interest, and is shown in Fig. 2. Despite the modest signal-to-noise ratio, four strong emission lines are clearly visible at $\lambda\lambda$ 4,450, 6,912, 7,750, and 7,980 Å. We identify these features as Mg II λ 2,800, H γ , H β and [O III] λ 5,007, respectively, and derive a galactocentric redshift $z = 0.594 \pm 0.001$, where the uncertainty is dominated by the breadths of the permitted emission lines. The galactocentric redshift of 3C345 (see refs 10, 11) is $z = 0.595$, where again we estimate a formal uncertainty of at least ± 0.001 due to emission line widths. Thus to within the measurement errors, the redshifts of these two quasars are identical. The spectra of the objects are at least superficially similar in appearance, although this is perhaps not surprising in view of the limited variety in the emission lines which are typically seen in QSOs at this redshift.

We may estimate the probability that the remarkable redshift agreement of the two objects is a chance coincidence of two randomly distributed, unrelated QSOs. Our X-ray observations⁶ yield 0.6 serendipitous sources per square degree, and we identify about half of these as QSOs with $z \leq 1$. Thus we expect to observe $\approx 6 \times 10^4$ QSOs before finding one with a

Fig. 1 A blue plate (IIa0 + GG385) of the field of the two quasars, obtained by Kinman with the Mayall 4-m telescope on 3 June 1973. The newly discovered quasar, 1641+3998, is the fainter of the two flagged objects, near the north-east of the field; 3C345 is the brighter object marked 8 arc min to the south-west.

'companion' as close in position (0.06 deg^2) and redshift (10^{-3}) as the current example is to 3C345. In fact only about 100 QSOs had been observed⁷ when 1641+3998 was discovered, so the probability of a chance coincidence is ~ 0.002 . Therefore, tempered by the hazards of a *posteriori* probability calculations, we conclude that the association of 3C345 and 1641+3998 is statistically significant and unlikely to be accidental.

If we accept the physical association of our two quasars, the explanations for such a situation are limited. We have briefly considered the extraordinary possibility that 1641+3998 could be a gravitationally focused image of 3C345, similar to the two currently known examples of this effect^{12,13}. The very large angular separation of the images compared with the previous cases would imply an unusual mass and/or mass distribution for the focusing matter. Remarkably this situation cannot be immediately dismissed, as a cluster of galaxies at $z=0.01$ with mass $2 \times 10^{14} M_{\odot}$ could create such an image. However, such a cluster must have a very extreme mass-to-luminosity ratio to avoid obvious detection. A more awkward difficulty with this hypothesis is that the ratio of fluxes of the two QSOs should be independent of wavelength. Although the optical and X-ray flux ratios of the two objects do agree well (within 3 orders of magnitude), 3C345 is an intense radio source (11 Jy at 178 MHz) leading to the prediction of an easily detectable radio flux from 1641+3998, barring long differential time delays. Maps which subtract the side lobes of 3C345 (ref. 14) do not show such a source, to limits of 10 mJy. The agreement of the ratio of optical and X-ray fluxes is thus probably simply a manifestation of the relative constancy of this parameter previously noted in large samples of radio-selected¹⁵ as well as X-ray selected⁶ QSOs.

The alternative hypothesis, which we favour, is that the redshift agreement of these two QSOs indicates their common membership in a cluster of galaxies. The projected separation of several Mpc would then indicate this to be a rich cluster, the first such example of a cluster with QSOs. Although theoretical calculations of cluster diameter evolution with redshift¹⁶ indicate that distant rich clusters should be smaller than at the current epoch, this poses no difficulty in the present case as these evolutionary effects become noticeable only at larger redshift. As the velocity dispersion in rich clusters of galaxies is as large as $1,500 \text{ km s}^{-1}$, one might worry that the observed small limit on the velocity difference between 3C345 and 1641+3998 ($\leq 300 \text{ km s}^{-1}$) implies a cluster velocity dispersion grossly inconsistent with this norm. However, this proves not to be the case. If for simplicity, the radial velocities of the cluster galaxies are assumed to have a gaussian distribution, then we can convert the observed difference between two members into 90% confidence limits on the actual dispersion. A 300 km s^{-1} difference between two cluster members implies a cluster dispersion in the range $100\text{--}3,000 \text{ km s}^{-1}$ (90% confidence). Thus, perhaps surprisingly, the small observed velocity difference is not an awkward constraint on this model. The virial mass implied for the cluster by this allowed range of dispersions is in the range $10^{13.5}\text{--}10^{16.5} M_{\odot}$, again, not restrictive, but consistent with the parameters of known rich clusters.

Our failure to detect X-ray emission from this putative cluster is not necessarily surprising, but means that the cluster has an X-ray luminosity less than about half that of the Coma cluster (the X-ray bright core of which would appear point-like at this distance). However, Einstein observations (F. Abramopoulos, personal communication) indicate this is not unusual even for rich clusters. In addition, if 3C345 lies close to the centre of the cluster, then the possibility of source confusion implies that the cluster will be even more difficult to detect in X rays.

Our hypothesis can be tested in that the normal galaxies in this putative cluster are expected to appear at $V=22\text{--}23$ and thus be directly observable. Good quality 4-m plates of the field obtained by Kinman do show numerous faint galaxies nearby. However, the space density of clusters at this faint apparent magnitude is large enough that two or three such clusters are expected on every high latitude 4-m plate¹⁷. Thus the prob-

Fig. 2 The spectrum of the quasar 1641+3998, obtained with the Lick 3-m Shane reflector, with $20\text{-}\text{\AA}$ spectral resolution. The data have been converted to relative fluxes above the atmosphere through observation of spectrophotometric standard stars, and the most prominent emission features are identified.

ability of a chance superposition of a faint, unrelated cluster on this pair of QSOs is not negligible, and radial velocities of the galaxies will be necessary to verify the proposed association.

Attention has recently been drawn to other close groupings of QSOs with similar redshifts¹⁸⁻²², and diverse interpretations involving clusters, superclusters and non-cosmological redshifts have been advanced. Whether these pairs, including the one discussed here, represent clusters or superclusters is of secondary importance to the broader conclusion that QSOs exhibit similar clustering characteristics as galaxies. The pair discussed here, being at low redshift, should be suitable for future research.

We thank Drs W. Reich, F. Abramopoulos and L. Lucy for useful discussions and correspondence, and Dr T. Kinman for permission to reproduce his 4-m plate. This work has been supported by the NSF and NASA; B. M. is an Alfred P. Sloan Foundation Research Fellow.

Random alignment of quasars

M. G. Edmunds & G. H. George

Department of Applied Mathematics and Astronomy,
University College, PO Box 78, Cardiff CF1 1XL, UK

Arp and Hazard¹ have reported several peculiar alignments of quasars, alignments which are exact to the limit of resolution on a Schmidt plate (2 arc s). We report here our investigation of the claim that the probability of such alignments occurring purely by chance is exceedingly small. Because the correct statistical analysis is not immediately obvious, we have performed a series of computer experiments to investigate how often such alignments will occur by chance.

Several trials were made in which 300 quasars were placed at random in two cartesian coordinates on a square, and each triplet of points whose overall linear extent did not exceed $1/7$ of the square side was examined for a possible alignment. Values of P , the deviation of the intermediate quasar from the line joining the other two members of the triplet, were determined. An example of the peculiar configurations that can arise by chance is shown in Fig. 1, taken from one of the trials.

The scale on the square depends entirely on the assumed density of quasars. Observational estimates² suggest that the density of quasars down to the twentieth magnitude is between 5 and 10 quasars per square degree. We have chosen a (possibly conservative) estimate of 6 quasars per square degree, (the value assumed by Arp and Hazard). On this scale, the whole square corresponds to approximately 50 square degrees of sky.

As the positions of all the quasars on the square (once placed) are known to very high accuracy, P is also known to high accuracy (corresponding to a resolution of a fraction of an arc s). In observations on a Schmidt plate, however, each image can be resolved only to 2 arc s, resulting in an uncertainty in alignment of somewhat more than 2 arc s. We have therefore chosen 2.4 arc s as a limit for P , below which we regard an alignment to be good. The number of alignments found (classified into various ranges of the value P up to 6 arc s) are shown in Table 1, the size

Table 1 The distribution of P (the displacement of the intermediate quasar of each triplet from a perfect alignment) for outer quasar separations $\leq 1^\circ$

P (arc s)	Mean of 16 runs	Largest no. in a single run	Smallest no. in a single run
0-0.24	1.6	4	0
0.24-1.20	7.4	15	4
1.20-2.40	7.9	14	4
2.40-3.60	7.4	19	2
3.60-4.80	9.4	16	5
4.80-6.00	8.2	12	5

limit on allowed alignments corresponding to 1° . Table 2 shows the number of alignments $P < 6$ arc s as a function of the separation d of the outer quasars of the alignment. χ^2 -tests indicate that these distributions are consistent with a uniform distribution in P , and a cubic distribution in d . Certain random alignments would, of course, run off the edge of the square, and thus be lost. This edge effect also occurs on Schmidt plates, but we believe that the proportion of alignments lost by this effect does not vary by more than about 10% between the square ($7^\circ \times 7^\circ$) and a typical Schmidt plate ($6^\circ \times 6^\circ$).

An estimate of alignment probabilities can be made by the following simple argument, although experience of Bertrand's paradox³ warns that such an estimate may only be correct to an order of magnitude. Let the number density of quasars be n per unit area, and consider any one quasar. Between a distance x and $x + dx$ of this quasar will lie $2\pi nx \, dx$ other quasars. A line between the first quasar and any one of these others will be of length x , and any quasars which will form triplets with distance P or less away from this line must lie within a rectangular area $2xP$, and the number of such quasars will be $2xnP$. Thus the number of alignments with the original quasar at one end is

$$\int_0^d 4\pi x^2 n^2 P \, dx = \frac{4\pi}{3} d^3 n^2 P$$

where d is the largest outer quasar separation we consider. For a plate of area A , the total number of quasars is nA , so neglecting edge effects and with a factor of $\frac{1}{2}$ to avoid counting each alignment twice, the total number of alignments N where the third quasar lies within a distance P of the line joining the other two is

$$N = \frac{2\pi}{3} A d^3 n^3 P$$

Table 2 The distribution of d (the separation of the outer two quasars of any alignment) for which $P < 6.0$ arc s

d (arc min)	Mean of 16 runs	Largest no. in a single run	Smallest no. in a single run
0-10	0.4	2	0
10-20	1.3	3	0
20-30	3.9	7	2
30-40	7.6	13	3
40-50	11.5	17	5
50-60	17.3	27	12

For comparison with the computer simulation we note $N \propto P$ and $N \propto d^3$ (as found); and if $A = 50$ square degrees, $n = 6$ per square degree, $P = 2.4$ arc s $= 6.7^\circ \times 10^{-4}$, $d = 1^\circ$ we gain $N = 15$, in excellent agreement with Table 1.

We have not considered the redshifts of the quasars. To do so would require detailed knowledge of the redshift frequency distribution, which is not well determined. Also, the cosmological interpretation of the quasar phenomenon allows for the redshift distribution to be quite independent of the distribution of quasars in the sky. Hence we could superimpose the redshifts on the existing data once the redshift distribution is sufficiently well known. Of course, one might expect one-third of the alignments to have the central quasar of lower redshift than the two outer ones. Also important may be observational selection of a central quasar on the basis of a bright magnitude, which would affect comparison with alignment probability estimates. However, for the present purposes we neglect magnitude effects (which are difficult to quantify and will be correlated with the redshift distribution).

Our computed results give an indication of how many good alignments might be expected on 50 square degrees of sky, and hence we would expect 11 alignments good to 2.4 arc s and of overall size less than a degree to appear on a typical Schmidt

F ⊙

Fig. 1 An interesting square of sky (from random distribution of quasars). A, B and C are aligned to less than 0.2 arc s and B, D and E to 1.0 arc s. Also note that F, G, D and H, E, J form very good alignments (to within 2.0 arc s).

plate. It is debatable whether these are too loose criteria, and comparison with Arp and Hazard's configuration depends critically on the assumed values of n , d and P . It is particularly difficult to quantify d , the overall separation of triplets searched for. We therefore also consider a more restrictive case, and take the largest alignment found as d . Their four quoted alignments have $d < 30$ arc min, and should it be found that $P \leq 1$ arc s, then for $n = 6$ per degree we estimate an expected number of alignments $N = 0.5$ per Schmidt plate, somewhat relaxed to $N = 2.5$ if $n = 10$. Arp and Hazard's find of four alignments (albeit on an incomplete search) lies between our loose and restrictive estimates and is anyway not too great a fluctuation difference from the restrictive one. We suggest that the evidence is not strong enough to require a ballistic theory to explain their observed configuration, it could well have arisen by chance. *A posteriori* statistics on a single configuration is never satisfactory, and a more definitive test might be made by identifying all probable quasars on the plate and testing the properties of their mutual alignments against the statistics for random distribution developed above.

We thank the director and staff of University College Computing Centre for computing facilities, Professor J. V. Narlikar for discussion, and particularly Dr B. F. Schutz for originally suggesting the use of random maps.

Precursor active galaxies and the cosmic X-ray background

Elihu Boldt & Darryl Leiter

Laboratory for High Energy Astrophysics, NASA/Goddard Space Flight Center, Greenbelt, Maryland 20771, USA

Data on the isotropic extragalactic X-ray background (>3 keV) obtained with the HEAO 1 A2 instrument¹ yield a spectrum over the energy band of maximum flux that is well described by a thermal model involving an optically thin hot plasma at a temperature of a half-billion degrees ($kT = 40 \pm 5$ keV). The spectra for known strong X-ray sources in the present epoch (active galaxies, clusters of galaxies) obtained with the same HEAO 1 instrument^{2,3} indicate that such objects at high redshifts cannot account for most of this background. On the other hand, deep-field exposures to soft X-rays (<3 keV) with the HEAO 2 Einstein Observatory⁴ suggest that discrete sources could be a sufficient explanation. This implies either (1) that these dim sources are generally unrelated to relatively bright nearby objects or (2) that they represent an earlier stage in their evolution. Short-lived thermal X-ray emission by galactic winds peculiar to an earlier epoch has been suggested⁵ as an explanation of the first kind, but the need for postulating new sources can be obviated if, as Leiter has argued⁶, prolific X-ray sources evolve in connection with active galactic nuclei involving massive compact objects. Here, we pursue the suggestion by Carr⁷ that most of the cosmic X-ray background (CXB) arises from thermal X-ray emission associated with black hole accretion disks for compact objects formed before galaxies but we favour a model where the onset of significant X-rays takes place within the epoch of galaxy formation at $z \leq 4$, when accretion disks are created by the interaction between massive black holes of pregalactic origin and young galaxies.

The spectral characteristics of the composite X-ray flux associated with the extragalactic sky is shown in Fig. 1. An extrapolation of power law (B) to the γ -ray regime ($> \frac{1}{2}$ MeV) suggests that such sources could well account for most of the

observed cosmic γ -ray background^{8,9}. But, as shown in Fig. 1, they can account for a relatively small part of the CXB.

For a survey limit of 2.6×10^{-14} erg cm⁻² s⁻¹ (1–3 keV), the deep exposures with HEAO 2 Einstein Observatory⁴ yield 19 ± 8 extragalactic sources deg⁻², comparable with the number of quasars¹⁰ brighter than $B \approx 20$ mag. Assuming that these sources have power-law X-ray spectra of energy index $\alpha = 0.7$ and that the slope a of the log N –log S relation at the survey limit and above is greater than unity, then these observed sources account for a percentage of the CXB which, at 3 keV, is given by $(a/(a-1)) (7.1 \pm 2.9)\%$. In Fig. 1, $a = 1.5$ (see ref. 4). A subsequent direct determination¹¹ of the log N –log S relation for these dim sources with HEAO 2, however, indicates that the slope is steeper and could be closer to $a = 2$. Yet, the log N –log S relation for quasars must flatten¹² as the number brighter than $B = 22.5$ mag is ≤ 50 deg⁻². The assumption that most of the CXB arises from quasars apparently gives a paradox for the required source count. Extrapolating the HEAO 2 source count through a log N –log S relation of constant slope a , for objects dimmer than the survey limit, we obtain that the number of sources required to account fully for the background is $\sim 2 \times 10^3$ sources deg⁻² for $a = 1.5$ and $\sim 10^3$ sources deg⁻² for $a = 2$. These estimates are an order of magnitude larger than the number of usual quasars considered which suggests that the onset of thermal X-rays precedes the formation of non-thermal radiating components.

The thermal-type spectrum observed for the CXB can be associated with two kinds of black-hole accretion disk radiation mechanisms: (1) bremsstrahlung from an optically thin hot plasma of the disk^{7,13}; (2) unsaturated Comptonization¹⁴ of soft photons by hot thermal electrons in the inner region of the disk, optically thin to absorption, where e^+e^- pair production cooling effects¹⁵ can limit the electron temperature (T_e) to $T_e \approx 2 \times 10^9$ K for a source luminosity close to the Eddington limit. The consistency of our model requires that the main sources of the CXB radiate at a level close to the Eddington luminosity limit. As case (1) is constrained to luminosities $\leq 1\%$ of this limit¹³, we concentrate on case (2). For reasonable sizes of the emitting hot optically thin inner disk region¹⁴ ($\leq 10^2$ GM/c²), e^+e^- cooling¹⁵ provides a thermostat whereby $kT \leq 0.2$ MeV, implying that $z \leq 4$ for most such sources of the CXB. The same condition applies to case (1) as the Gaunt factor for optically thin thermal bremsstrahlung emission at $kT \geq 0.2$ MeV would fail to provide an acceptable fit to the CXB spectrum observed (R. Shafer, personal communication). This suggests that there is no accretion disk during a black-hole accretion phase earlier than that corresponding to $z \approx 4$. For photon energies much less than the observed redshifted value of $kT \sim 40$ keV the CXB exhibits an effective energy spectral index^{1,3} $\alpha \approx 0.4$. In this restricted regime, the CXB spectrum may be synthesized by a superposition of sources having power-law spectra with $\alpha \approx 0.4 \pm 0.1$ (G. DeZotti, personal communication). For a source temperature fivefold higher than that observed for the CXB (that is, $(1+z) 40$ keV = 200 keV), case (2) provides acceptable spectral indices for values of the Kompaneets parameter ($y \approx 1-2$)

Table 1 PAG sources of the CXB

Central mass $M_0 \leq 1$ ($M_0 = 10^{-9} M/M_\odot$)
Black-hole specific angular momentum $0 \leq a/M < 0.998$ ($a = J/M$)
Luminosity (10^{47} erg s ⁻¹) (0.4–1.3) M_0
Number (4–8) $\times 10^7$
Thermal characteristics
Temperature: 2×10^9 K
Size: $\leq 10^2$ GM/c ² = $(2 \times 10^{16} M_0)$ cm
Emission mechanism: unsaturated comptonization (with Kompaneets parameter $y = 1-2$)
Redshift $z = 4$; $\Delta z = 0.3$ ($q_0 = 0.01$) or $\Delta z = 0.4$ ($q_0 = 0.5$)
Composite luminosity (10^{44} erg s ⁻¹) [*] = 1.4 ($q_0 = 0.01$) or 0.3 ($q_0 = 0.5$)
Co-moving density (10^{-4} Mpc ⁻³) [*] = 1 ($q_0 = 0.01$) or 7 ($q_0 = 0.5$)

^{*} For $h = H_0/(100 \text{ kms}^{-1} \text{ Mpc}^{-1}) = 0.5$ where H_0 = Hubble constant and q_0 = deceleration parameter.

characteristic of the model¹⁴. For photon energies $E \approx kT$, all these power-law spectra are modified by the required exponential tail-off: $\exp(-E/kT)$.

We start with Carr's suggestion that black holes are generated and evolve towards masses up to $\sim 10^9 M_\odot$ by pregalactic processes beginning at $z > 100$. However, the thermostat associated with the temperature observed for the CXB would imply that these black holes develop significant accretion disks at $z \leq 4$. Before the formation of these disks, random pregalactic processes which involve spherical accretion are not expected to be efficient for X-radiation¹⁶. Therefore, the X-radiation associated with accretion must be relatively unimportant until galaxy formation processes supply the matter associated with an ample accretion disk. Furthermore, pregalactic processes associated with random accretion should not cause appreciable spin-up of the black holes because the capture cross-section for negative angular momentum particles (opposite to the hole's spin) is greater than that for positive angular momentum¹⁷. Beginning at $z \leq 4$, within the epoch of galaxy formation, these massive black holes acquire significant accretion disks for the first time and become the 'seeds' which distinguish precursor active galaxies (PAG) from galaxies which will evolve normally. These PAG sources of the CXB postulated here are characterized in Table 1. In this model, these PAG objects would be the thermal sources of the sort required for the CXB, but necessarily cooler than previously considered ($kT \leq 0.2$ MeV). In the process of disk accretion on a time scale of $\sim 10^8$ yr, however, the central massive black hole of a PAG could increase in mass by a factor of ~ 1.5 and be spun-up¹⁸ to a 'canonical Kerr hole'. By this time black hole ergospherically induced²⁰ electron-positron injection^{6,19,33} could trigger and surge electromagnetic disk-dynamo mechanisms^{21,22}. Furthermore, the efficiency for energy transfer to the relativistic particles required for non-thermal radiation processes (such as synchrotron) could by then begin to increase appreciably, as the size of the acceleration region grows^{23,24}. Hence, during transition, there may be some young active galaxies which are not yet sufficiently luminous non-

thermal disk-dynamo synchrotron sources to be readily identified as such while their thermal disk X-ray emission is still large.

The spin-up of a black hole due to a radiating accretion disk reaches an equilibrium 'canonical' value¹⁸ ($a/M \approx 0.998$) when the hole's mass increases by $\sim 1.5 M$ (initial). Assuming that the radiation efficiency (ϵ) is constant and that the luminosity (L) is proportional to the Eddington limit (L_{Edd}), this increase of mass is achieved in a time (Δt) after the formation of the accretion disk, given by

$$(\Delta t) = 4 \times 10^8 \epsilon (1 - \epsilon)^{-1} R^{-1} \text{ yr} \quad (1)$$

where $R \equiv L/L_{\text{Edd}}$. In such conditions the black hole mass and size increase exponentially with a characteristic growth time given by equation (1). More realistically, ϵ changes during the accretion process. Initially, when $\epsilon \approx 0.06$, this growth time could be as short as 3×10^7 yr (for $R \approx 1$). At spin-up¹⁸, however, $\epsilon \approx 0.3$ and the characteristic time for further growth would be at least an order of magnitude longer (with $R < 1$). If the accretion rate is then 'starved' by a high angular momentum configuration of remaining gas, such as in a spiral galaxy, we might expect $R \ll 1$ and that any further growth within a Hubble time ($\sim 10^{10}$ yr) is relatively minor. The amorphous nature of the spiral galaxies associated with Seyfert nuclei may well be caused by a process which slowly feeds material from outer regions into the centre²⁵.

By the time of spin-up, given by equation (1), the innermost stable orbit of the accretion disk has amply penetrated the ergosphere²⁶, and electron-positron injection processes⁶ associated with a canonical Kerr black hole are 'switched on'. The time (Δt) to reach this state is the effective lifetime of the PAG phase. This canonical state of spin is insensitive to small ($< 10\%$) fluctuations in the matter accretion rate and the counter-torques due to radiation¹⁸. In this context, the evolution of a PAG into a system involving a massive canonical Kerr hole may be viewed as an essentially irreversible process. Such behaviour is of the type needed for describing the observed evolution²⁷ whereby the sources of the CXB (for example, PAG objects at $z \leq 4$) lead directly to the active galaxies observed at later epochs. As a broad band of non-thermal radiation can eventually be generated at a relatively high efficiency²⁸ (at the expense of weakened thermal disk emission^{21,22}), the thermal disk component could be masked for many of the brightest active galaxies, but might sometimes be observable. In this connection, the spectrum measured for the quasar 3C273 is consistent²⁹ with a substantial contribution from a thermal X-ray component at $T \geq 10^9$ K, while the broad-band X-ray spectrum of QSO 0241+622 is incompatible with such a feature³⁰. The PAG objects associated with Seyfert nuclei might involve galaxies where the amount of gas available for accretion from a low angular momentum configuration (for example, in a central bulge) is not large compared with that of the initial black hole. In this situation (such as one involving a spiral galaxy) we expect that a luminosity as high as 10^{47} ergs s^{-1} (Eddington limit for $10^9 M_\odot$) could not last much beyond spin-up. For appreciably longer time scales we assume $R \ll 1$; the resulting active galaxies could thereby survive to be observed in the present epoch (for example, as Seyfert galaxies) with much lower luminosities but with non-thermal spectra extending well into the γ -ray band.

The thermal component of the CXB corresponds to a surface brightness of 2.0×10^{-7} erg $(\text{cm}^2 \text{ s sr})^{-1}$. For a Friedman cosmology with $q_0 \leq 0.5$, $H_0 = 100 h \text{ km s}^{-1} \text{ Mpc}^{-1}$ and with most sources of the CXB at $z \approx 4$, the bolometric luminosity for the sum of all these sources, in their proper frame, is $\Sigma L \geq 8 \times 10^{52} h^{-2} \text{ erg s}^{-1}$. The number of sources required for the CXB is $N(\text{CXB}) \approx (4-8) \times 10^7$, so the implied average bolometric luminosity per source ($\bar{L} \geq 10^{45} h^{-2} \text{ erg s}^{-1}$) is readily associated with the PAG objects postulated here as the limit $R > 0.3$ is required to constrain the PAG lifetime from being much greater than $\sim 10^8$ yr (see equation (1)). If the central black hole were initially much less massive than $\sim 10^7 M_\odot$, then it would take substantially more than 10^8 yr (beyond spin-up) to

Fig. 1 Spectral density for the surface brightness of the extragalactic X-ray sky as a function of photon energy. The 'total flux' curve is the best-fit thermal spectrum ($kT = 40$ keV) for the background measured by Marshall *et al.*¹. The power-law A represents the composite flux due to sources detected above the survey limit in the HEAO 2 deep exposures by Giacconi *et al.*⁴. The power-law 'B' represents the composite flux from active galaxies with $z \leq 1$, based on the local luminosity function determined³ with HEAO 1 A2 and assuming no evolution, with $q_0 = 0$. The dashed lines are extrapolations.

grow towards a mass where the luminosity could reach the level required here for sources at $z \approx 4$. Hence, such objects would not qualify as PAG sources of the CXB.

The total number of PAG objects $N(\text{PAG})$ making up the CXB is fixed by the model in terms of the local density of active galaxies. A fundamental aspect of this model is that the density of PAG objects in co-moving coordinates remains constant during the time (Δt) of spin-up and that the co-moving density of active galaxies after production equals that of the associated PAG objects. Assuming that the PAG population is produced at a look-back time corresponding to $z = 4$, $N(\text{PAG})$ is given by

$$N(\text{PAG}) = (1.4 - 8.9) \times 10^8 \phi \Delta \tau h^{-3} \quad (2)$$

where the limits indicated correspond to $q_0 = 0.5$ and $q_0 = 0.01$ respectively, $\Delta \tau$ (units of age of the universe) is the look-back temporal interval of the PAG phase, and ϕ is the co-moving density of PAG objects (in units of 10^{-4} Mpc^{-3} , the value measured²⁵ for the local density of Seyfert galaxies and consistent with the local luminosity function for X-ray active galaxies³ in the luminosity range $\sim 10^{42} - 10^{45} \text{ erg s}^{-1}$ (3–50 keV)). For $\phi \geq 1$ and $\Delta \tau \approx 10^{-2}$ (corresponding to $\sim 10^8 \text{ yr}$) equation (2) indicates that the number of PAG objects could well match the number of sources required for the CXB: $N(\text{CXB}) \approx (4 - 8) \times 10^7$. The total mass involved in all the pregalactic black holes that precipitated these sources would be less than 10^{-4} of the known mass in galaxies. When most PAG objects are within $\Delta \tau = 10^{-2}$ at $z \approx 4$ then $\Delta z < 8 \times 10^{-2}(1+z)$, ensuring that the fractional spread in observed temperatures due to redshift would be $< 8\%$, compatible with the CXB spectral data.

We conclude that most of the CXB could be generated by distant sources that are not usual active galaxies or quasars, and that they must have a relatively low ratio of optical to X-ray luminosity (that is dominantly X-ray objects). PAG objects at $z \leq 4$ involving a massive ($\leq 10^9 M_\odot$) black hole surrounded by a hot optically thin accretion disk radiating near the Eddington luminosity limit with an effective temperature $\sim 2 \times 10^9 \text{ K}$ would meet this condition and yield the correct CXB spectrum and intensity. Furthermore, this model has the advantage of providing an evolutionary track which links both the CXB and the non-thermal γ -ray background directly to active galaxies, implying that massive ($\leq 10^9 M_\odot$) black holes are indeed associated with their internal dynamics (as suggested by X-ray observations³¹ involving temporal variability). While the PAG sources of the CXB postulated here would have low optical continuum emission relative to quasars, strong emission lines comparable with those of quasars generated from a broad-line region photoionized³² by the central X-ray source could lead to a direct identification of these objects. As the average X-ray flux expected from a PAG is an order of magnitude below the survey limit for the HEAO 2 Einstein Observatory, they would not be well represented in the 'complete' sub-sample observed, but some of the dimmest unidentified objects detected should be considered candidates.

Measurement of ionospheric winter anomaly in Southern Hemisphere

Brian G. Ferguson

Ionospheric Prediction Service, Department of Science and the Environment, PO Box 702, Darlinghurst, 2010 Sydney, Australia

The unexpectedly high ionospheric radio-wave absorption that occurs during winter at temperate latitudes is referred to as the 'winter anomaly'. These variations have been attributed to increases in the concentration of the minor atmospheric species NO and O₂(¹Δ_g), themselves important in the formation of the D-region. This anomaly involves an order of magnitude increase of the electron number density which, in turn, leads to an increase in the absorption experienced by radio waves propagating in the D-region. The phenomenon occurs between 75 and 95 km, with the maximum enhancement near 80–83 km (ref. 1). We describe here a period of anomalous absorption observed at Camden, Australia (34°S, 151°E), during 15–17 June 1980. This anomalous event is significant because previous observations of the winter anomaly have, in general, been restricted to the Northern Hemisphere, especially Europe and because our observation was made at a lower latitude than those suggested^{2,3} as the low-latitude boundary of the winter absorption anomaly. Previous measurements in the Northern Hemisphere have placed the low-latitude boundary at about 37°N (for the 1968–69 winter²) and 35°N (for the 1971–72 winter³). The second measurement suggested an increase of 1 dB per degree of latitude above the boundary. The magnitude of the anomalous absorption in our measurements, at 34°S, was 10 dB. The magnitude of this absorption suggests either that this event was very large or that the ionospheric response is different in the two hemispheres.

The A1 (or pulse amplitude) method for measuring ionospheric absorption involves the measurement of the amplitude of radio-wave pulses reflected vertically from the ionosphere. An automatic A1 system, which uses a micro-processor for both the various system control functions and the signal processing has been described elsewhere⁴. The equipment was installed at Camden, New South Wales, in December 1979 and operates on a frequency of 1.91 MHz. A sample of the amplitude data (3-min medians) for 20 June 1980 is plotted in Fig. 1 as a function of local time (GMT + 10 h) between 08.00 and 16.00 h.

A convenient technique for characterizing the diurnal variation in the amplitude data is to fit a second-degree polynomial (quadratic) to the observations by using least-square methods. For instance, the quadratic which best fits the observations for 20 June between 08.00 and 16.00 h is shown in Fig. 1. The scatter of points about this (solid) curve is attributed mainly to either non-dissipative amplitude fluctuations (fading) or to variations in the reflection mode. In addition, solar X-ray events can cause the data points to depart significantly (by $> 10 \text{ dB}$) from the quadratic curve describing the normal daily variation in the amplitude data. The ionospheric response to X rays of short

Fig. 1 A1 amplitude data (3-min medians) for the period 08.00–16.00 h, 20 June 1980. The full curve represents the second-order polynomial of best fit through the data points.

wavelengths ($<10 \text{ \AA}$) is to increase the concentration of electrons in the D-region through ionization of the neutral atmosphere. This is accompanied by an increase in the absorption suffered by radio waves as they travel through the region of enhanced electron density.

The quadratic curves of best fit (one for each day) for the periods 8–20 June (solid curves) and 4–11 July (broken curves) are superimposed in Fig. 2. A1 data for the intervening period were not available. Solar X-ray events during these periods were either of small intensity (C class events) or of small duration ($<1 \text{ h}$), which indicates that the ionospheric response was not large enough to modify significantly the coefficients of the quadratic curves of best fit. However, this was not true for the data collected on 6 July, during which a large (M9) X-ray event produced an absorption increase of at least 60 dB between 08.40 and 09.05 LT. Consequently, the A1 amplitude data associated with this event were omitted in determining the quadratic curve for 6 July.

Fig. 2 Quadratic curves of best fit for the A1 amplitude data for the periods 8–20 June (solid curves) and 4–11 July (broken curves). The days that exhibit marked anomalous absorption are 15, 16 and 17 June 1980. Numbers on the curve indicate days of the month.

Figure 2 shows that the days of 15–17 June were characterized by amplitude values which were consistently below those for the other days. Thus 15–17 June are classified as days which exhibited anomalous absorption. The minimum amplitude values of the quadratic curves associated with these anomalous days are $\sim 10 \text{ dB}$ less than those for the adjacent days of 14, 18 and 19 June. However, by considering days remote from the anomalous period (say 10 June and 10 July), the anomalous absorption seems to be $\sim 15 \text{ dB}$. If the latter estimate of the magnitude of

Fig. 3 Minimum values of the daily quadratic curves of best fit for the Camden A1 data, together with a histogram of the Canberra $f_{\min}$ data (median of the 3-h values), plotted for the periods 8–20 June and 4–11 July 1980. $\square$, 08.00–10.00 h; $\square$, 11.00–13.00 h; $\blacksquare$, 14.00–16.00 h LT.

the anomalous absorption is adopted, then the period associated with the winter anomaly can be extended to include 14, 18 and 19 June. Thus the anomalous absorption for 14, 18 and 19 June was ~3 dB, while for 15–17 June it was ~15 dB.

The winter anomaly in absorption also manifests itself in the Canberra (35°S, 149°E) ionosonde data. The appropriate parameter is $f_{\min}$ which is the lowest frequency at which an echo returned from the ionosphere can be detected on an ionogram. This parameter is observed to increase as absorption increases, for example, during solar X-ray flares. However, $f_{\min}$ is also affected by factors extraneous to ionospheric absorption, for instance, equipment characteristics and radio-frequency interference. Figure 3 shows the medians of the scaled $f_{\min}$ hourly values for the periods 08.00–10.00, 11.00–13.00 and 14.00–16.00 h using a histogram format for the periods 8–20 June and 4–11 July. For comparison, a graph of the minimum values of the quadratic curves of best fit for the A1 data is also shown for the same periods. The days characterized by enhanced $f_{\min}$ values coincide with days for which the absorption was anomalously high.

The above preliminary analysis indicates that a period of anomalous absorption occurred during the winter of 1980 in the Southern Hemisphere. The A1 amplitude data from Camden indicated that the anomalous absorption had a lower limit of 10 dB and may have been as high as 15 dB, depending on the reference level. Enhanced $f_{\min}$ values were recorded on the anomalous days by an ionosonde located in Canberra. The results show that an asymmetry exists between the Northern and Southern Hemispheres with respect to winter anomalous absorption. Predictions based on data from only the Northern Hemisphere were found to be inappropriate as they failed to explain the existence of anomalous absorption at Camden. This suggests that the experimental programmes aimed at collecting data on the aeronomic (physical, chemical and dynamical) behaviour of the stratosphere/mesosphere during the forthcoming Middle Atmosphere Programme (1982–85), should be conducted in both hemispheres. The results should be analysed separately (according to hemisphere) rather than combining them into one data base which would average-out any asymmetry. Also, global aeronomic models should reflect the differences that exist between the hemispheres.

I thank George Daniel for assistance with the diagrams.

Inorganic lead complexation in natural seawater determined by UV spectroscopy

Robert H. Byrne

Department of Marine Science, University of South Florida, St Petersburg, Florida 33701, USA

Recent effort to construct trace metal complexation models in natural media^{1–8} is a mark of the importance of chemical form in the biogeochemical behaviour of trace metals. Unfortunately such chemical modelling is difficult in many ways. Chemical speciation models of trace metals in complex natural media such as seawater are usually constructed using stability constants determined in simple media. We describe an alternative procedure which can reduce the errors inherent in this approach. Using UV spectroscopy, we have examined lead speciation in seawater. The method is a means of describing metal speciation in seawater quantitatively using stability constants determined exclusively in seawater. Preliminary experiments indicate that the same approach can be used for other metals including copper.

Speciation models for lead in seawater (Table 1) alternatively predict: (1) that only lead carbonate complexes¹ are important; (2) that lead carbonate species are unimportant and that lead chloride complexes are dominant^{2,3}; (3) that lead hydroxide complexes are important^{4,5}; and (4) that lead hydroxide complexes are unimportant⁶. Sipos *et al.*⁵ have described two models of lead complexation in seawater. In their second model, they adopt the chloride speciation scheme of Johnson and Pytkowicz⁹ and the concentration ratio of their dominant lead species, $\text{PbOH}^+/\text{PbCO}_3^0$, diminished by a factor of 3.5 compared with the first model. Three factors explain the observed variability of models. (1) Stability constants are selected from a wide range of values. (2) Stability constants are generally determined in simple media and adapting these constants to seawater conditions introduces error. (3) Minor element speciation schemes depend on the speciation schemes adopted for the major constituents of seawater. Our approach eliminates the latter two sources of error, and provides an essential test of the various models constructed for lead speciation in seawater.

Lead chloride complexation experiments used unfiltered surface seawater (34.7‰ salinity) from the Gulf of Mexico which was enriched in lead (~7 μM in Pb(II)) with an acidic lead stock solution. The UV absorbance characteristics of these solutions were measured between 300 and 220 nm against a lead-free seawater reference solution. The test solution, housed in a 10-cm pathlength spectrophotometric cell, was acidified with varying amounts of 1 M HCl, producing a series of absorbance versus pH curves at 25 °C (Fig. 1). Cells were sealed except during measurements of pH. For each absorbance versus wavelength curve (Fig. 1) the solution pH ($-\log A_{\text{H}}$) was determined with a micro combination pH probe (Micro-electrodes Inc.) calibrated on the NBS scale. Experiments were conducted at the naturally occurring total CO_2 concentration, 2.05×10^{-3} mol total CO_2 per kg seawater. Total CO_2 and M_{CO_3} , the total carbonate ion concentration, were calculated from pH and the initial carbonate alkalinity^{10,11} using the apparent constants of Mehrbach *et al.*¹².

The isosbestic point observed at 237 nm in Fig. 1 indicates that adsorption is not significant. The strong pH dependence demonstrates that lead is not exclusively complexed with chloride ions in seawater. PbCO_3^0 and PbOH^+ are thought to be important at high pH. Varying the pH of a lead-enriched seawater solution between 3.9 and 8.2 causes molar-absorptivity changes between 220 and 300 nm which are highly dependent on the seawater's total CO_2 content. The molar-absorptivity change is $<250 \text{ M}^{-1} \text{ cm}^{-1}$ at zero total CO_2 and as large as $1,400 \text{ M}^{-1} \text{ cm}^{-1}$ at the natural CO_2 concentration, 2.05×10^{-3} mol per kg seawater. The much larger change when carbonate is present suggests that PbOH^+ is much less significant than PbCO_3^0 . Hence plots of absorbance versus pH at constant wavelength will be distinctly different for different total CO_2 concentrations, and absorbance versus $\log M_{\text{CO}_3}$ at different pH will be nearly identical (Fig. 2).

The results of five experiments were analysed quantitatively: three at total CO_2 2.05×10^{-3} mol per kg seawater and two at total CO_2 9.84×10^{-3} mol per kg seawater. Assuming PbOH^+ is insignificant compared with PbCO_3^0 , the absorbance of lead in seawater can be described by^{13,14}:

$$_{\lambda}A = \frac{_{\lambda}\epsilon_0 + _{\lambda}\epsilon_1\beta_1 \cdot M_{\text{CO}_3}}{1 + \beta_1 \cdot M_{\text{CO}_3}} \quad (1)$$

where $_{\lambda}A$ is absorbance at wavelength λ , M_{CO_3} is the sum concentration of carbonate species (such as, CO_3^{2-} , NaCO_3^- , MgCO_3^0 , and CaCO_3^0), $_{\lambda}\epsilon_1$ is absorbance due to PbCO_3^0 , $_{\lambda}\epsilon_0$ is absorbance due to the lead forms which dominate at low pH (principally Pb^{2+} , PbCl^+ , PbCl_2^0 and PbCl_3^-) and β_1 is the formation constant of PbCO_3^0 .

Lead-absorbance data were analysed at four wavelengths (240, 250, 260 and 270 nm) which did not require corrections for baseline variability with pH. Absorbance data at these

Table 1 Species composition of inorganic lead in seawater

Model-species	Ref. 2*	Ref. 3	Ref. 7	Ref. 4	Ref. 5†		Ref. 8	Ref. 6	Ref. 1
PbCO ₃ ⁰ , Pb(CO ₃ ²⁻) ₂ ²⁻ , PbCO ₃ Cl ⁻	—	<1	18	40	22	47	65	77	100
PbOH ⁺ , Pb(OH) ₂ ⁰ , PbOHCl ⁰	2	15	5	33	49	30	6	1	—
Pb ²⁺ , PbCl ⁺ , PbCl ₂ ⁰ , PbCl ₃ ⁻ , PbSO ₄ ⁰	98	84	73	27	28	23	28	21	—

Composition is given as a percentage of the total inorganic lead at pH 8. Totals <100% indicate that additional complexes contribute to the speciation scheme.

* The Morel and Morgan² model was constructed for a hypothetical system which is quite similar to seawater in ionic strength and the free concentrations of Cl^- , CO_3^{2-} and H^+ .

† The Sipos *et al.*⁵ model is constructed for pH 8.1.

wavelengths in five experiments were fit using equation (1) in a non-linear least-squares analysis^{13,14}. At 25.0 °C and 34.7% salinity:

$$\beta_1 = \frac{M_{\text{PbCO}_3}}{M_{\text{Pb}} \cdot M_{\text{CO}_3}} = (10.0 \pm 0.3) \times 10^3 \quad (\text{mol per kg seawater})^{-1} \quad (2)$$

where M_{PbCO_3} is the concentration of PbCO_3^0 and mixed ligand carbonate species^{8,15,16}, and M_{Pb} is the sum concentration of Pb^{2+} , PbCl^+ , PbCl_2^0 , PbCl_3^- and less significant species. This PbCO_3^0 formation constant enables $M_{\text{PbCO}_3}/\text{total Pb}$ at 25.0 °C

Fig. 1 Absorbance per molar cm of $\text{Pb}(\text{II})$ in natural seawater as a function of wavelength and pH. (Temperature 25.0 °C; salinity 34.7%; total CO_2 : 2.05×10^{-3} mol per kg seawater.) Absorbance data are corrected for baseline variation with pH at wavelengths <235 nm.

and 34.7% salinity to be calculated when total CO_2 and pH are known. M_{CO_3} is calculated from total CO_2 and pH (see refs 11, 12). The fraction of total lead present as PbCO_3^0 can then be determined without knowledge of the ion pairing interactions of CO_3^{2-} with the major cationic seawater constituents, and there is no formation constant variation between seawater and the test medium.

Using equation (2) at 25.0 °C, 34.7% salinity and total CO_2 of 2.05×10^{-3} mol per kg seawater it can be shown that $M_{\text{PbCO}_3}/\text{Total Pb} \geq 0.5$ for $\text{pH} \geq 7.85$. As seawater generally

contains a greater total CO_2 concentration, PbCO_3^0 seems to be the dominant form of inorganic lead in seawater.

Expansion of equation (1) to account for the possible existence of PbOH^+ , PbHCO_3^+ and $\text{Pb}(\text{CO}_3)_2^{2-}$ in the test medium produced β_1 values similar to that in equation (2). Although formation constants for the species PbOH^+ , PbHCO_3^+ and $\text{Pb}(\text{CO}_3)_2^{2-}$ were ill-defined suggesting that these species were present only in low concentration, the analyses did produce upper 95% confidence limits which are useful for estimating the importance of each species in seawater (Table 2). The formation constant determined for PbHCO_3^+ indicates that this species has little significance ($M_{\text{HCO}_3} \approx 2 \times 10^{-3}$ mol per kg seawater). From its formation constant, PbOH^+ is unlikely to constitute more than 10% of the total inorganic Pb in seawater ($\text{pH} \leq 8.3$). From the β_2 upper 95% confidence limit, $\text{Pb}(\text{CO}_3)_2^{2-}$ and PbCO_3^0 could be present at approximately equal concentrations in seawater ($M_{\text{CO}_3} \approx 3 \times 10^{-4}$ mol per kg seawater), but the existence of well defined isosbestic points makes this improbable. If $\text{Pb}(\text{CO}_3)_2^{2-}$ were present at appreciable concentrations, its molar absorbance at 237 nm would have to be identical to that of PbCO_3^0 to produce the observed isosbestic point.

The present analysis requires that a 7 μM lead enrichment would not significantly alter the inorganic complexation of lead in seawater. This is satisfied because the appropriate ligands have concentrations $\gg 7 \mu\text{M}$. The most unfavourable molar ratio, total $\text{CO}_2/\text{Pb}(\text{II})$, is >290 . Consequently, calculated values of M_{CO_3} are more affected by small experimental errors in measurement of pH than by lead enrichment, enabling this description of inorganic lead complexation to be applied to natural seawater.

Our lead carbonate formation constants are strongly influenced by the ion pairing interactions of carbonate ion and possibly chloride ion with the major cationic constituents of seawater. However, as our methods do not require any particular model of these interactions, our formation constants and conclusions are independent of these descriptive models.

Constants of the form defined by equation (2) allow the pH dependence of Pb speciation in seawater to be described without assuming that activity coefficients are constant in diverse media at constant ionic strength. Our conclusions that the dominant

Table 2 Results of formation constant determinations in natural seawater at 25.0 °C and 34.7% salinity

Species considered	Formation constants determined
PbCO_3^0	$\beta_1 = 10.0 \times 10^3$
PbCO_3^0 , PbHCO_3^+	$\beta_1 = 9.4 \times 10^3$; $\text{HCO}_3\beta = \frac{M_{\text{PbHCO}_3}}{M_{\text{Pb}}M_{\text{HCO}_3}} \leq 14.5$
PbCO_3^0 , PbOH^+	$\beta_1 = 10.3 \times 10^3$; $\beta_1 = \frac{M_{\text{PbOH}^+}A_{\text{H}}}{M_{\text{Pb}}} \leq 2 \times 10^{-9}$
PbCO_3^0 , $\text{Pb}(\text{CO}_3)_2^{2-}$	$\beta_1 = 12.3 \times 10^3$; $\beta_2 = \frac{M_{\text{Pb}(\text{CO}_3)_2}}{M_{\text{Pb}}M_{\text{CO}_3}^2} \leq 7.3 \times 10^7$

Concentrations of all chemical species except H^+ are defined on a mol per kg of seawater concentration scale. Hydrogen ion activities, A_{H} , are operationally defined on the NBS scale¹¹.

Fig. 2 Absorbance per molar cm of Pb(II) in seawater as a function of pH and $\log M_{\text{CO}_3}$ at 25.0 °C and 34.7‰ salinity. Total CO_2 is 2.05×10^{-3} mol per kg seawater ($\Delta \diamond$) or 9.84×10^{-3} mol per kg seawater ($\blacksquare$). Dashed lines are coordinated on the pH axis. The solid line is coordinated on the $\log M_{\text{CO}_3}$ axis.

inorganic species of lead in seawater are PbCO_3^0 and lead chloride species are consistent with the models of Turner and Whitfield⁸ and Zirino and Yamamoto⁶.

Other trace metals such as iron (III) and copper have intense absorbance spectra in the UV. The methods used here can be extended to investigations of the chemistry of iron and copper in natural media. Preliminary experiments indicate that studies of copper in seawater can be conducted within the natural pH range of seawater. The plasticity of the copper (II) coordination sphere¹⁷ suggests that the activity coefficients of copper species may be significantly influenced by medium composition, and hence that the 'natural medium approach' may be especially useful.

The age of the Weddell Basin

John L. LaBrecque

Lamont-Doherty Geological Observatory, Columbia University, Palisades, New York 10964, USA

Peter Barker

Geophysics Section, University of Birmingham, Birmingham B15 2TT, UK

The deep oceanic basin occupied by the Weddell Sea separates the East Antarctic craton from the Antarctic Peninsula, a largely post-Palaeozoic orogenic belt. An understanding of the tectonic evolution of the basin would resolve most of the remaining problems of Gondwanaland reconstruction, which revolve around the relative positions of these two fragments and South America. Norton and Sclater¹ conclude that Indian Ocean marine geophysical data essentially support the Smith and Hallam fit², but the unacceptable overlap of undoubtedly old continental crust^{3–5} on the Antarctic Peninsula and Falkland Plateau implies relative motion between the Peninsula and East Antarctica. Such motion is not required by the reconstruction of Barron and others^{7,8} which, however, can be criticized on other grounds^{9,10}. The marine geophysical observations within the intervening ocean basins have proved useful in formulating plate tectonic reconstructions. Fracture zone trends, seafloor spreading type magnetic anomalies, crustal heat flux, and crustal depth all provide clues to the timing and direction of the continental motions. The acquisition of geophysical data from the Weddell Sea region has been slow^{11–13}. However, the combined interpretation of the two largest data sets extant^{12,13} now being undertaken, seems likely to provide a more tightly constrained Gondwanaland solution. As a first step, we report here an estimated age for the Weddell Sea floor in the area bounded by 60° and 73° S, 5° and 35° W shown in Fig. 1.

Figure 1 also shows the tracks of cruises 1277 and 1578 of ARA Islas Orcadas in the Weddell Basin. Line drawings of seismic reflection profiles obtained on three long north-south lines during these cruises form Fig. 2. A zone W at 64°–65° S¹² separates a more northern area of much greater basement relief from the more southern area being considered here. In this northern area, fracture zone orientations are highly oblique to the gross orientation of the magnetic lineations^{12,13} but the more subdued basement topography to the south suggests that fracture zones there are subdued and have only small offsets. The general depth of the basement increases southwards and, when corrected for sediment loading, is consistent with a Mesozoic age^{12–14} in the area south of zone W with younger crust to the north.

Figure 3 shows our age model for the oceanic crust which floors the Weddell basin. The magnetic anomaly profiles plotted in Fig. 3 are from ref. 13 and are augmented by data collected aboard ARA Islas Orcadas and Project Magnet Flight 720. Note that the magnetic anomalies display a strong east-west lineation and seem to converge to the west. They are compared in Fig. 3 with a magnetic model covering the time period 162–35 Myr. (anomalies M29–13^{15–17}). Seafloor spreading rates vary from 0.6 cm yr⁻¹ during the early Cretaceous to 0.9 cm yr⁻¹ during the Palaeogene. To model the smoothing effect of finite polarity transition zones within the oceanic crust we have convolved the magnetic polarity model with a gaussian function ($\sigma = 3$ km)¹⁸. Rather than assume a magnetic pole position for the anomaly sequence, we have assigned a value of zero skewness to the pattern¹⁹. This effectively defines a family of probable pole positions though we must also account for anomalous skewness²⁰. The choice of zero skewness is based largely on the apparent symmetric nature of anomalies 33–34. All other anomalies can accommodate variations of up to $\pm 30^\circ$ in the model skewness.

Fig. 1 Map of Weddell Basin showing regional location of Fig. 3. Tracks of *Islas Orcadas* cruises 1578 and 1277 are shown superimposed upon the regional bathymetry in meters²⁹. Encircled letters illustrate locations of seismic reflection profiles of Fig. 2.

Figure 3 also shows synthetic fracture zones or flow lines (stippled lines) calculated for the various reconstructions of Norton and Sclater¹. The flow lines display the displacement of a point on the Antarctica–South America spreading centre with respect to Antarctica fixed²¹. The flow lines are small circles about stage poles calculated for South America motion with respect to Antarctica fixed. We have included flow lines for an M13 reconstruction assuming that the change in plate motions required by the initiation of seafloor spreading in the South Atlantic^{22,23} was accommodated by a change in Antarctica–South America relative motions.

The spreading rates and directions inferred from the calculated flow lines match the observed data reasonably well with two exceptions. The flow line which represents crustal generation during the interval M1–34 (Cretaceous Normal) was reduced in length by 80% from that predicted by the Norton and Sclater poles. This suggests either a significant error in the

Norton and Sclater reconstructions for the time period, or an asymmetry in the seafloor spreading process such as a southward jump of the spreading centre. The dramatic change in spreading direction required by the opening of the South Atlantic in the Valanginian is not observed in the magnetic lineation pattern though a gradual reorientation of the anomaly pattern is perceived.

The strong lineation shown by anomalies 33–34 is consistent in direction and spreading rate with that predicted for Antarctica–South America motion at the Agulhas Magnetic Bight²⁴. The Weddell anomaly 33–34 sequence is a westward extension of the same anomaly sequence observed by Bergh and Barrett²⁵ north-west of the Maud Rise. The calculated lineation direction of the Bergh and Barrett sequence is in error, however, because of their assumption of symmetric seafloor spreading within the Agulhas Basin at the Africa–South America (or Malvinas) spreading centre²⁴.

Fig. 2 Line drawings taken from *Islas Orcadas* seismic reflection profiles located in Fig. 1. The locations of identified magnetic anomalies are indicated below each profile. Station numbers are from ref. 26.

Fig. 3 Magnetic anomaly profiles in the Weddell Sea from Islas Orcadas cruises and Project Magnet flight 720. Model parameters: layer depth, 6 km; layer thickness, 500 m, skewness parameter $\theta=0$; transition zone width, $w=12$ km; magnetization, 0.01 emu cm^{-3} , spreading rates: 35–80 Myr BP = 0.9 cm yr^{-1} , 80–108 Myr BP = 45 cm yr^{-1} , 108–165 Myr BP = 0.6 cm yr^{-1} . Flow lines for South American motion with respect to Antarctic fixed are shown as stippled lines and are explained in the text. Ages along flow lines are expressed as magnetic anomalies and are underlined.

Heat flow measurements taken on board Islas Orcadas cruise 1578 reveal a general northerly increase in heat flux within the Weddell Basin²⁶. High heat flow values observed within the Weddell Basin have led to proposals that the Weddell Basin may have formed as a marginal basin during Tertiary times²⁶. The data presented above strongly suggest a much older age for the Weddell Basin. In Figure 4 ages are assigned to the Weddell heat flow stations using the age model presented in Fig. 3, and the Weddell heat flow stations are compared with the global mean values compiled by Parsons and Sclater¹⁴. The high values observed at stations 55 and 40 have been discussed by Zlotnicki *et al.* and may be accounted for by local basement peaks (station 55) and the general variability of individual heat flow values.

The data and model presented above is a first step in tracing the separation of South America and Antarctica since the

breakup of Gondwanaland. Our interpretation of the geophysical data including fracture zone trends, depth to basement, magnetic anomaly lineations, and heat flux indicates that the southern Weddell Basin is pre-late Jurassic to Cretaceous in age. Basement age becomes progressively younger to the north and is Cenozoic in age north of Zone W. We conclude that the Weddell Basin in the area studied was formed at the southern flank of a spreading centre. The northern flank has probably been subducted beneath the Scotia Sea^{12,27,28} or parts may be trapped within it⁶. The general conformity of the observed spreading pattern with that predicted along several lines of evidence for South America–Antarctic relative motion suggests that the spreading centre formed the South American–Antarctic plate boundary throughout much of the breakup of Gondwanaland. The westward convergence of the Weddell magnetic lineation

Fig. 4 Comparison of Weddell Basin heat flow values (○) with the Parsons and Sclater heat flow curve (●) using the proposed basement ages.

pattern suggests that the poles of rotation which describe the separation of Antarctic–South America are located very near the Antarctic Peninsula.

Transcurrent faulting and the anomalous position of pre-Carboniferous Anglesey

M. J. C. Nutt & E. G. Smith

Institute of Geological Sciences (NERC), Ring Road Halton, Leeds LS15 8TQ, UK

The marked differences of pre-Carboniferous geology between Anglesey and of mainland North Wales are accounted for by Devonian transcurrent faulting probably caused by stresses resulting from the closure of the Iapetus Ocean. Displacement along this fault is thought to have exceeded 100 km, so that the Lake District and not Anglesey would formerly have been in juxtaposition with North Wales.

The Carboniferous Limestone of Anglesey can be closely correlated with that of the North Wales mainland¹, so that in Viséan times the two areas probably had the same geographical relationship as today with continuity of sedimentation between them. There is no reason to suppose that the underlying Carboniferous Basement Beds of the two areas do not have a similar relationship. This is in accord with the concept of a Lower Carboniferous sea encroaching southwards from the Irish Sea Basin onto a landmass of older rocks².

These older rocks present a very different picture. The Precambrian of Anglesey consists of a bedded series of arenaceous and argillaceous sediments with subordinate basic volcanics—the Mona complex^{3,4}—ranging in metamorphic facies from greenschist to amphibolite. The only comparable rocks on the mainland are those of southwestern Llyn⁵ and of the River's Mouth Formation at Caernarvon^{3,6}. The Precambrian of the mainland—the Arvonian—consists essentially of acid and intermediate volcanics (of the Bangor and Padarn ridges⁶ and of Brynteg Borehole⁷ in the Harlech Dome), which have suffered only a low degree of metamorphism. Unless these rocks are represented by the Baron Hill Beds and the Bwlch Gwyn

Felsite^{8,9}—an unlikely correlation—the Arvonian seems to be absent in Anglesey.

Greenly³ provisionally assigned several small outliers in Anglesey, including those of the Careg-onen Beds and the Trefdraeth Conglomerate, to the Cambrian, but later¹⁰ considered them to be older. The only fossils recorded in Anglesey that may be of Cambrian age are stromatolites^{11,12} and microfossils¹³ from the Gwna Group, supposed by Greenly³ to be Precambrian rocks. The rocks containing the stromatolites, however, are associated with mélangé and therefore may be derived blocks in much younger deposits. Indeed, there is stratigraphical evidence (unpublished) showing that at least part of the Gwna Mélangé is of Ordovician age. Whether Cambrian rocks are absent in Anglesey or whether they are represented in the Mona Complex (as the above evidence and the stratigraphical interpretation of Barber and Max¹⁴ suggest), there is a marked contrast with the mainland where, only a few kilometres away across the Menai Strait, are some 2,000–3,000 m of slates and grits. Moreover, these latter rocks apparently overlie the Arvonian conformably or with no great unconformity.

The Ordovician rocks of Anglesey, ranging up to basal Caradoc¹⁵, differ from those of the mainland in several major respects. The generally black mudstones of the former contrast with the predominantly grey silty mudstones of the latter, and there is a greater development of arenaceous rocks in Anglesey. Volcanic rocks, which form such a significant part of the mainland Ordovician sequence, are unknown in Anglesey with the probable exceptions of the Fydyln Felsite¹⁴ and the relatively thin lavas and tufts underlying the Middle Llandovery sediments at Parys Mountain¹⁶. Mélanges, a feature of the Ordovician of Anglesey, where they range in age from Arenig to Caradoc, have not been recorded elsewhere in North Wales. In contrast to the mainland, there is evidence of a major pre-Caradoc unconformity in Anglesey¹⁵. This may extend throughout the island, but is best demonstrated in the north, where Caradoc sediments apparently rest on Llanvirn, Arenig and Monian rocks. Upper Caradoc and Ashgill rocks are absent in Anglesey, with the possible exception of the thin volcanics separating Llandovery (*M. argenteus* Zone) and Llanvirn (*D. bifidus* Zone) shales at Parys Mountain. The Ordovician shelly faunas of Anglesey, like those of south-east Ireland and Ramsey Island, Pembrokeshire, have Celtic (Baltic) affinities, whereas those of mainland Wales belong to the Anglo-French (Anglo-Welsh) province^{17–20}.

The only known Silurian rocks in Anglesey are ~50 m of shales at Parys Mountain, attributable to three graptolite zones of the Llandovery. Unlike the equivalent rocks on the mainland, these contain bands of lithic tuff¹⁶. Assuming that the volcanics underlying the Llandovery rocks at Parys Mountain are of Ordovician age, the lower part of the Llandovery sequence of the mainland, which is conformable on the Ordovician, is absent in Anglesey.

The Old Red Sandstone is absent in North Wales except in Anglesey, where it is represented by some 500 m of conglomerates, sandstones and siltstones, probably belonging to the southern British development²¹.

The structure of the Lower Palaeozoic rocks of Anglesey is clearly related in both form and trend to that of the basement. There is evidence that Ordovician sedimentation was controlled by renewed movement on structures within the Mona Complex¹⁷. Although the basement has not been proved on the mainland, it seems most unlikely that the structure of the Lower Palaeozoic rocks reflects that existing in the basement at depth.

This account of fundamental geological differences between Anglesey and the mainland points out the anomalous position of the island with respect to the rest of North Wales in pre-Carboniferous times, suggesting that the two areas did not come into juxtaposition before the late Devonian. So far as the Precambrian is concerned, separation into an oceanic and a continental plate can be effected by a subduction zone—along the Penmynydd Zone of Metamorphism in southeastern Anglesey. Activity on such a zone can perhaps be extended to Tremadoc times—to the end of the Avalonian orogenic

event^{7,22}. During the Ordovician and Silurian periods, however, the operative subduction zone must have lain much farther to the north-west, beyond Anglesey and the Lake District. Closure of the Iapetus Ocean is invoked to account for faunal contrasts between the Ordovician Scoto-Appalachian and Celtic provinces, but the differences between Anglesey and mainland North Wales, belonging respectively to the Celtic and Anglo-French provinces, have not been satisfactorily explained²⁰.

Plate tectonics alone, therefore, do not seem to provide a solution to Anglesey's anomalous position, and it is suggested here that the answer might be found in transcurrent faulting. A northeasterly trending dextral fault with a lateral movement of at least 100 km is envisaged in the vicinity of the Menai Strait (Fig. 1). Such a fault would have a greater displacement than the parallel sinistral Great Glen Fault, but be of lesser magnitude than the subparallel dextral fault postulated²³ along the Iapetus Suture, across Ireland and through the Solway. It has been suggested²⁴, however, that the Great Glen Fault may have undergone up to 100 km of post ~400 Myr dextral movement, and there is doubt²⁵ about the magnitude of the movement along the Iapetus Suture.

The credibility of this speculative transcurrent fault between Anglesey and the rest of North Wales depends on finding areas of compatible geology that could have been adjacent to each before the fracture occurred. In the case of the North Wales mainland the appropriate area is the Lake District.

The oldest known rocks in the Lake District are pelitic and arenaceous sediments of the Skiddaw Group, ranging in age from Arenig to Llanvirn. These are comparable to sediments of similar age in North Wales and, like them, contain volcanics—the mid-Arenig tuffs and lavas of the southwestern Lake District²⁶, and the Llanvirn Eycott Volcanics of the northern Lake District²⁷. The Eycott Volcanics are interpreted as the tholeiitic belt of an island-arc environment, and the overlying Llandeilo to Caradoc Borrowdale Volcanics as the calc-alkaline belt²⁸. The Ordovician volcanics of North Wales have been interpreted as part of the calc-alkaline belt in this setting²⁸. Southwards and later this belt gives way to alkaline volcanics. The proposed

transcurrent fault, bringing the two calc-alkaline areas closer together and reducing the width of the belt, as well as eliminating Anglesey from the picture, is advantageous to this model.

Apart from the locally deposited Coniston Limestone and associated beds at the base, the rest of the Lower Palaeozoic sequence in the Lake District is closely comparable with that of mainland North Wales, and it is not unreasonable to suppose that the two sequences were deposited in juxtaposition. The Ashgill Shale Formation²⁹ of the Lake District is lithologically similar to the Bodeidda-Deganwy Mudstones of the Conway area³⁰, the Rebecca Grit of the former³¹ correlating with the Conway Castle Grit of North Wales. The two Llandovery sequences are virtually identical, the Skelgill Beds of the Lake District equating with the succession below the Pale Slates of the Conway area, and the Browgill Beds with the Pale Slates themselves². In the Wenlock there is a marked lithological similarity between the turbiditic Brathay Flags and the Lower Nantglyn Flags, the Lower Coldwell Beds of the Lake District and the Denbigh Grits Group of Wales being proximal facies derived at different times from the west. A prominent band of calcareous concretions in the *Cyrtograptus centrifugus* Zone near the base of the Denbigh Grits Group² compares with a similar band in the same zone in the Lake District and Howgill Fells²⁹. The Middle Coldwell Beds are lithologically identical to the Mottled Mudstones of the Denbigh area, the upper leaf of the former²⁹ having the same zonal position (*Monograptus ludensis*) as the Upper Mottled Mudstone. In the Ludlow the Upper Coldwell Beds equate with the Upper Nantglyn Flags, and the overlying Coniston Grits and Bannisdale Slates are the recognizable equivalents of the lower and upper parts of the Elwy Group respectively. The Coniston Grits are derived dominantly from the north-west²⁹, whilst the slump sheets with sandstones at the same horizon in Wales come from the west². Higher Silurian horizons exposed in the Lake District are not known in North Wales.

The trends of the Caledonian folding in the Lake District and North Wales, swinging from SW-NE to W-E towards the east, show a better fit when the two areas are in north-south

Fig. 1 Map showing the proposed transcurrent fault and the pre-Carboniferous (Silurian) positions of Anglesey and the Lake District relative to Wales. The line of the fault approximates in the north-east to the Dent Line, passing southwestwards beneath Carboniferous and later cover to run along the Menai Strait (the Dinorwic Fault), where transcurrent movement has previously been deduced¹⁴ from the extensive development of mylonites. The fault crosses the Lleyn (where it may have been dislocated by subsequent transcurrent faulting) from Porth Nefyn to the western side of Hell's Mouth, confining the Precambrian rocks, which have affinities with Anglesey, to its north-western side and separating substantially different Ordovician sequences^{5,36-38}.

juxtaposition than in their present geographical positions (Fig. 1).

If the Lake District and the North Wales mainland are matching parts of an Ordovician island-arc sequence and of a Silurian basin of sedimentation torn apart by the proposed transcurrent faulting, we must look southwestwards for the area originally adjacent to Anglesey, if it still exists. The obvious candidate is south-west Wales (Pembrokeshire and Carmarthenshire). Here, although the Cambrian is markedly unconformable on the Precambrian and there are Ordovician faunal similarities between Ramsey Island and Anglesey as well as agreement between the heavy mineral assemblages of the Old Red Sandstone of Pembrokeshire and Anglesey²¹, the general affinities of south-west Wales are with the North Wales mainland. Thus the Uriconian-type volcanic sequence composing the Precambrian of Pembrokeshire compares with the Arvonian rather than the Mona Complex, there is a thick Cambrian succession, an Ordovician sequence containing limestones, thick volcanics and no recorded mélanges, and, in west Pembrokeshire, a well developed Silurian succession extending through the Wenlock and Ludlow into the Downtonian.

Anglesey is more comparable with southeastern Ireland. The Precambrian para- and ortho-gneisses with mylonites of the island and of the Lleyn Peninsula¹⁴ are not dissimilar from those of the Rosslare Complex³². The basic intrusions forming the Rosslare dyke swarms³³ may be represented in Anglesey by basic dykes cutting gneisses, for example, at Treferwyd¹⁴. The Coedana Granite of Anglesey and the Sarn Granite of the Lleyn belong to the same orogenic episode as the Carnsore Granite intruded into the Rosslare Complex³⁴. The New Harbour Group of Anglesey is similar to the ?Precambrian Cullenstown Formation¹⁴ and the South Stack Formation to the Lower to Middle Cambrian Bray Group³. As in Anglesey, there is a pre-Caradoc unconformity in southeastern Ireland, though the overlying rocks of the latter, the Duncannon Group, are predominantly volcanic³⁵. There is insufficient detailed knowledge of the Llandovery rocks of southeastern Ireland to attempt a comparison with Anglesey. Structural trends (east-northeasterly to northeasterly) in this part of Ireland are similar to those in Anglesey. The form of the folds in the Irish Lower Palaeozoic is also reminiscent of the situation in the Monian and Ordovician of Anglesey.

The line of the proposed transcurrent fault is shown in Fig. 1.

South-west of the Lleyn the fault probably runs down St George's Channel to lie off the coast of south-east Ireland (Fig. 1), but possibly swings farther west through Rosslare Harbour and along the mylonite zone of the Rosslare Complex^{14,39,40}, separating the gneisses of the latter from the rest of Ireland. An offshore position is favoured, however, because of geophysical evidence of a major fault in this region^{41,42} and the likelihood that the northern boundary of the subsequent Celtic Sea Basin⁴³ corresponds to the line of such a major pre-existing fault^{39,40,44}.

A dextral movement of at least 100 km is envisaged along the proposed fault (Fig. 1). This movement not only removes Anglesey from its present incongruous proximity to North Wales, but creates a more rational relationship between the latter area and the Lake District. A more southwesterly location for Anglesey would also bring the Silurian tuffs of the island closer to the zone of known Silurian volcanism extending from the Dingle Peninsula, through Skomer, to the Mendips⁴⁵. Similarly a more southerly position for the Lake District diminishes the inclination of a southeasterly dipping Lower Palaeozoic Benioff Zone originating along a trench approximately through the Solway. K_2O/SiO_2 plots for Borrowdale volcanic rocks (unpublished data) suggest, following studies of potash-depth relations⁴⁶, that the depth of the Benioff Zone below the central Lake District was of the order of 235 km. This gives a dip from the Solway (allowing for 50% crustal shortening⁴⁷) of $\sim 65^\circ$, an excessive figure in comparison with that quoted⁴⁶ for modern continental margin arcs ($\sim 40^\circ$). The re-location of the Lake District as in Fig. 1 gives a Benioff Zone dip

of $\sim 45^\circ$, which angle would be further reduced by a more southwesterly Ordovician location.

The cause of the dextral transcurrent movement can be looked for in NW-SE compressional stresses following the final closure of the Iapetus Ocean in Devonian times, the same explanation invoked²³ for similar lateral movement on the line of the Iapetus Suture itself. Major transcurrent movements affecting the Caledonides of the British Isles and North America in the mid-Devonian and extending over ~ 20 Myr are indicated by palaeomagnetic studies⁴⁸.

The Devonian movement may have been merely the culmination of dextral wrenching initiated in the Cambrian or Precambrian. Whilst Fig. 1 shows the best fit of the Lake District and North Wales for the Silurian rocks, there is evidence that a more southwesterly position for the Lake District would be better for a match of the Ordovician rocks of the two areas. The fault might, therefore, date back to the Cambrian or Precambrian and its line might have been dictated by the position of the Penmynydd subduction zone during its active lifetime. This situation would be similar to, for example, the present position in New Zealand, where, at an active plate junction, there is an intimate relationship between the subduction zone forming the Kermadec-Tonga Trench and the subparallel strike-slip Alpine Fault⁴⁹.

It is feasible that major northerly and northwesterly faults in North Wales and northwestern England originally developed as conjugate fractures to the proposed transcurrent faulting. The age (around 355 Myr as shown by K-Ar dating) and direction (ENE-WSW) of the main suites of metalliferous veins in Anglesey (Parys Mountain¹⁶), the Lake District (Vale of Newlands⁵⁰), Central Wales (Plynlimon mining field⁵¹) and Salop (Shelve area⁵¹) suggest that these veins may occupy tensional structures associated with dextral transcurrent faulting of the proposed trend, a situation in keeping with the theory⁵² of hydraulic fracturing.

Evidence of syndimentary tectonic movements in the Triassic halite of Cheshire

Roger M. Tucker & Maurice E. Tucker

Department of Geology, The University, Newcastle upon Tyne NE1 7RU, UK

During the Triassic, north-west Europe was subjected to tensional stresses which resulted in the formation of a complex system of rapidly subsiding grabens and wrench-faulted basins. This pattern of regional crustal extension, which is part of the larger scale Mesozoic break-up of the Pangean megacontinent, is related to the Triassic opening of the Tethys Ocean in southern Europe and rifting in the Arctic North Atlantic, and is a prelude to the Jurassic opening of the southern North Atlantic¹. Great thicknesses of generally continental sediments, often with salt deposits, accumulated in the Triassic basins, which were mainly avolcanic. In western Britain, a complex series of fault-bounded basins extended from the Western Approaches and Channel area northwards to the Irish Sea, and includes the Worcester graben and the Cheshire Basin. The present study of the halite formations in the Cheshire Basin shows evidence for pencon-temporaneous fault movements; these were a feature of Triassic times but it is rare that such movements can be detected so precisely as is the case here.

The Cheshire Basin is filled with Triassic sediments dating from the Anisian (lower Middle Triassic) and reaching several kilometres in thickness^{2,3}. There are two thick halite developments in the sequence: a lower Northwich Halite Formation (290 m) and an upper Wilkesley Halite Formation (400 m)⁴. Each of these consists of a series of halite units up to 40 m thick separated from each other by horizons of dolomitic silty clay ('marl'). Between the halite formations, and above and below, there are thick formations of marl of the Mercia Mudstone Group, previously referred to as the Keuper Marl. In the ICI mine at Winsford, Cheshire, where these studies were undertaken, halite is being extracted from two beds in the lower part of the Northwich Halite Formation.

Fig. 1 Photograph of the roof of the mine at Winsford, Cheshire, showing large-scale polygonal pattern (polygon is 14 m wide).

Although principally flat-lying, the halite units in the Cheshire Basin are locally folded into monoclinical structures, which may impart a 45° dip on the beds. The trends of the monoclines are controlled by faults in the underlying Carboniferous basement. Several of the monoclinical structures, trending NE–SW, occur in the area now being mined at Winsford.

The Cheshire halite shows well defined bedding on a scale of 10–50 mm, resulting from an alternation of pure and less pure halite. The salt was deposited from standing bodies of water which were at most only several metres deep⁵. Bromine analysis indicates a marine source for the water (R. M. T., in preparation), although the nearest seawater at the time would have been many hundreds of kilometres distant in southern or northernmost Europe.

On bedding surfaces of the halite, best seen on the roof of the mine, spectacular polygonal patterns are present^{6,7}. These polygons are up to 14 m wide and are defined by 0.5 m-thick bands of secondary salt interlayered with clastic material (Fig. 1). Extending down to 6 m from the polygons, and so seen on mine walls, are tapering V-shaped fissures, with the same layered fills. The layering in the fissures is arranged as a series of

Fig. 2 Sketch from photograph of the wall of the mine at Winsford, Cheshire, showing deep V-shaped fissures and upturned bedding between each fissure.

10 mm wide subvertical bands running parallel to the sides of the fissure. Notably, the fine bands in the fissure fills are paired with a mirror-symmetry about a central unit of secondary salt. Bedding in the halite is upturned adjacent to the fissures (Fig. 2). We propose that each of the clastic layer pairs represents a single opening and filling of the original crack. Capillary brine drawn up the crack, from an underlying ground water table, precipitated the secondary halite. The highly layered nature of the fissure fills thus represents successive openings and fillings of the crack.

The formation of the polygons and fissures is attributed to a process of thermal contraction, acting on the halite after its deposition when it was subaerially exposed⁷. The formation of thermal contraction polygons in halite is very similar to that of periglacial polygons where thermal contraction of ice is involved⁸. Indeed, the thermal properties of salt and ice have much in common, both having high coefficients of linear thermal expansion. When an exposed salt surface is subjected to temperature fluctuations a polygonal pattern, defined by open fissures extending down into the salt bed, is formed during colder periods. The open fissures may then be filled with clastic material transported to the area by wind or water. During subsequent surface temperature increases, the salt surface re-expands and causes compaction of the clastic fissure fill material.

contraction-crack infilling-expansion of the surface salt causes bending up of the salt beds adjacent to the fault. The polygons in Cheshire show that there were long intervals of exposure and non-deposition after evaporation to dryness of the water body from which the halite was precipitated.

It can be demonstrated⁷ that the thermal contraction cracks were induced by temperature fluctuations operating over an annual period. Such temperature fluctuations are well documented from modern deserts, including Death Valley, California, where dry salt lakes with polygonal cracks are known⁹.

In some areas of the mine at Winsford, polygons are not developed, but in their place stripes occur. These form two linear belts, trending NE-SW, which can be traced across the whole mine area. The internal layering of the stripes and their associated fissures are identical to those of the polygons and their fissures, so that a process of thermal contraction was also involved. The location and orientation of the linear stripe patterns are significant: they run parallel to the axes of two monoclinical fold structures and are only developed close to the upthrow side of the monoclines, where they replace the polygons (Fig. 3).

Patterns of stripes associated with polygons have been described from several locations^{10,11}. Neal¹¹ demonstrated that stripes would form in sediments subjected to desiccation if they were located on a slope. The sediments would be pre-stressed, because of the effects of gravity, so that on contraction the stress pattern would be mirrored in the pattern of desiccation fissures produced: that is, a striped pattern which trends normal to the dip of the slope. Striped patterns on slopes associated with polygons are also found in the periglacial environment in ice-rich sediments. A process of thermal contraction (but of ice) is also involved, but where stripes form, they are always orientated parallel to the dip of the slope. The reason for this is that ice-rich sediments have the ability to flow downslope. This has the effect of modifying the original polygon form through several phases from stretched polygons to stripes orientated down the slope.

The striped patterns in the Cheshire halite are thus taken to indicate the development of a slight slope on the surface of the halite which must have been the result of contemporaneous movements on the underlying basement faults. That the stripes in the halite are parallel to the monoclinical fold axes, and thus normal to the dip of the slope that existed, shows that the movements on the faults caused the salt above the fault to become stressed, due to the bed being stretched over the fault. When thermal contraction cracking affected the newly exposed salt surface, polygonal patterns formed on the unstressed areas away from the fault-monoclinical axes and striped patterns following the stress pattern formed on the pre-stressed areas above the basement faults.

The thermal contraction polygons and stripes in the Triassic Cheshire halite show that there were contemporaneous movements on Carboniferous basement faults. If the fault movements occurred after thermal contraction cracking had begun, the

resultant crack pattern close to the upthrow side of the fault would be extremely complex, being made up of both polygons and stripes. However, the striped areas in the Winsford mine have a very simple pattern containing only stripes. This then indicates that the fault movements must have occurred either immediately after halite precipitation had ceased, and the salt bed became emergent, or during salt deposition, and it was this movement that caused the salt bed to become subaerially exposed. It is likely that such movements affected sedimentation in the Cheshire Basin in other ways, such as contributing towards the periodic cutting off of the Cheshire Basin from its distant marine water source, and affecting the siliciclastic supply for the basin by controlling rates of uplift of surrounding highlands.

We thank ICI Mond Division for permitting us to undertake geological studies in the salt mine at Winsford. R.M.T. acknowledges NERC for financial support during this study, and both authors acknowledge the respective Tucker wives.

Functional reconstruction of gait from the Pliocene hominid footprints at Laetoli, northern Tanzania

J. Charteris, J. C. Wall & J. W. Nottrodt

School of Human Biology, College of Biological Science, University of Guelph, Guelph, Ontario, Canada N1G 2W1

Direct measurements of fossilized Pliocene hominid footprints yield only spatial information, such as the length and angle of step¹⁻⁴. A more complete description of gait requires temporal information so that parameters such as the number of steps taken per minute (cadence) or speed of walking can be calculated. The relationships between step length, cadence and speed of walking have been worked out for modern man and regression equations of high predictability are available⁵. When measurements from the hominid footprints are fitted to these equations a pattern of gait emerges which contradicts previous reconstructions. As we report here, the pattern of gait consistent with the reported footprint measurements from Laetoli is one that might be described as 'strolling', in which the stride is quite short, even when related to the maker's height.

The data reported from Laetoli include the lengths of each foot (*l*) and 'stride', but contrary to the most widely accepted convention the latter actually represent steps or half-strides. Usually stride-length (*L*) is defined as the distance between two consecutive points of contact by the same foot, which means that a stride is made up of two steps. This distinction between step and stride is critical in attempting to reconstruct gait. White⁴ has assessed the stature (*S*) of the makers of the Laetoli footprints; he used data obtained from modern, small people, the Mawabi Pygmies, whose mean foot-length he found to be equivalent to 15.5% of stature. Independent assessment of stature of the East African hominids agrees that they were very small^{6,7}. Thus, from the measurement of stride-length and the estimated stature we can calculate relative stride-length (*L'*).

$$\text{Relative stride-length, } L' = \frac{\text{Stride-length (m)}}{\text{Stature (m)}}$$

Fig. 3 Schematic block diagram showing the relative positions of polygons and stripes in the ICI mine at Winsford.

Fig. 1 Graph of stride-length (in units based on fractions of stature) against speed (in units based on fraction of stature covered overground per second) for a normal adult population. In the small portion of the range of relative speeds relevant to this analysis the relationship is linear. The bar on the ordinate reflects the normal range of relative strides available to human adults. The relative speeds of the early hominids whose footprints have been reported indicate a slow traverse across the Laetoli ash beds. Table 1 shows how the ordinate values for hominids leaving trails 1 and 2 are obtained.

Measurements of gait, such as time and length of stride, vary with walking speed. When walking together, at a speed calculated in standard units such as m s^{-1} , a tall and a short subject have very different step-lengths and cadences, the shorter individual having to increase one and/or the other, in order to 'keep up'. These differences in gait due to stature may be factored-out by measuring speeds in units of body length covered overground per second^{5,8,9}; thus:

$$\text{Relative speed, } V' = \frac{\text{Velocity (m s}^{-1}\text{)}}{\text{Stature (m)}}$$

Table 1 Gait parameters measured and derived from the Laetoli footprints

Measure	Units	Symbol	Hominid trails		Source or derivation
			1	2	
Foot-length	m	<i>l</i>	0.185	0.215	Direct measurements
Stride-length	m	<i>L</i>	0.774	0.944	Ref. 2
Foot-length-per stride	—	<i>l'</i>	4.18	4.39	
Stature	m	<i>S</i>	1.19	1.39	$S = 100l/15.5$ Ref. 4
Relative stride	Stat	<i>L'</i>	0.65	0.68	$L' = L/S$
Relative speed	Stat. s^{-1}	<i>V'</i>	0.47	0.52	$L' = [60 V'(1 - \beta_2)]/\alpha_2$ Ref. 5
Velocity	m s^{-1}	<i>V</i>	0.56	0.72	$V = V'S$
Stride time	s	<i>T</i>	1.38	1.31	$T = L/V$
Cadence	Steps min^{-1}	<i>C</i>	87	92	$C = 120/T$

The curvilinear equation for predicting V' from L' is

$$L' = \frac{60 V' (1 - \beta_2)}{\alpha_2} \quad (1)$$

where constants $\alpha_2 = \pm 63$ (males), ± 69 (females), and $\beta_2 = 0.58$.

Figure 1 plots relative speed against relative stride using Grieve's equation and our own data collected from a population of 13 normal young adult caucasian Canadians (6 males, 7 females). Using the measured stride-length and estimated stature, it is possible to calculate values for the relative strides of the early hominids and to use these values to estimate relative speed (Fig. 1).

We use here data from footprints of the two hominids reported by Leakey and Hay² from site G in fossil locality 8 at Laetoli. They assigned the 22 smaller prints to one individual, designating these as trail 1, and the 12 larger prints to a second individual, assigned to trail 2. (Evidently there is far more assurance of these trails than of those found at site A.) The data measured from the footprints at site G, together with the gait parameters derived from them, are shown in Table 1.

Given that modern man normally walks at about 0.86 relative speed^{5,9}, it can be seen from Fig. 1 and Table 1 that the Laetoli hominids walked slowly (around 0.50). Recognizing that in modern man almost every measurable aspect of gait is related to speed, we suggest that in field work the walking speed can be

Fig. 2 Graph of stride-lengths in units of foot-length against relative speed, for the same normal young adult human group, showing mean values ± 1 s.d. Based on the relative speed assessment from Fig. 1, the appropriate ordinate values, measured directly off the substrate are plotted, confirming without need of stature estimates of the hominids that their pattern of gait was essentially human.

determined on the basis of the foot-length and the length of stride, which can be measured directly from a set of footprints. Through the most used portion (0.4–1.0) of the range of relative speeds open to modern man there is an approximately linear relationship between the number of foot-lengths in one stride and relative speed (Fig. 2). Thus, even without estimates of stature it is possible to determine whether the gait was slow, medium or fast, and whether footprints made side-by-side are likely to suggest individuals walking along together or traversing the same path but at different speeds and times. Figure 2 confirms our reconstruction of slow speeds, not just slow in human terms, but slow even for these small hominids.

We have not intended to make definitive statements about the characteristic gait of the Laetoli hominids, but rather to show workers in the field how they might reconstruct gait patterns of early bipedal hominids when further trails of footprints are found. Our calculations using data published from Laetoli are based on certain assumptions: that the measurements made on the footprints are accurate, that the prints are indeed those of

early bipedal hominids and that in any sequence of two or three prints only one individual is represented. We used White's estimate of stature⁴, but even using the upper and lower limits from White's tables, and values from groups other than the Mawabi Pygmies our conclusions would not be substantially altered.

If we assume that the relative proportions of the feet of Pliocene hominids are essentially the same as those of modern man⁴, and that their gait was functionally equivalent¹⁰, our determinations of the walking patterns of the hominids (Table 1) are valid, for they are the values that would be expected from modern human subjects of small stature.

Our reconstruction challenges previous claims³ that the stride is "... quite long relative to the creature's small size". On the contrary, it is quite short relative to its maker's stature. Grieve¹¹ has given the adult range of relative strides (Fig. 1) from which it is apparent that a relative stride-length ~0.65 is closer to the lower end of the normal range. Normal young adults select 'comfortable' or 'preferred' walking speeds remarkably close to the 0.86 relative speed^{9,12,13}. Grieve^{5,11,14} has pointed out that walking speeds are situation dependent, but we believe that unless some environmental or motivational constraint was acting on these hominids to walk slowly (in the sense of cautiously), the patterns thus far reported from the ashfall tuff of Laetoli are patterns consistent with what humans call 'strolling'. In these conditions there is no need to invoke a narrow step-width or variable step-angle as evidence of a pattern in any way different from that of modern man; normal humans, strolling at around 0.4 relative speed, often exhibit the same features.

Firefly mate-rivals mimic their predators and vice versa

James E. Lloyd

Department of Entomology and Nematology, University of Florida, Gainesville, Florida 32611, USA

Fireflies, beetles of the family Lampyridae, use flashes of bioluminescent light for sexual communication—by means of coded patterns, males and females identify and locate each other in darkness¹. In sexual signalling of *Photinus macdermotti* (eastern United States) the male emits two flashes separated by ~2 s and the female then waits ~1 s before replying with a single flash (Figs 1a, 2a)². Females of *Photuris versicolor* and *Photuris 'B'* mimic the reply of *P. macdermotti* females thus attracting *P. macdermotti* males, which they eat (Fig. 1b, c). When the predators are decoying *P. macdermotti* males, they sometimes produce 'extra' flashes that mimic the 'competition' flashes used by the males when competing for females (compare Fig. 1d with e)³. I suggest here that the male competition flashes (that the predators mimic) might also be mimics of the predator's own mimicry.

This complex interaction, the apparent product of a long co-evolutionary 'arms' race⁴, is more comprehensible when a model for its evolution is considered (Fig. 3). The predators also

mimic the responses of single-flash species⁵ and it is of special importance to the model that predators became tuned to *P. macdermotti*'s double flash only after they mimicked and preyed on single-flash species. Mimicry mistakes during this evolutionary transition initiated the path to the 'meta-mimicry' proposed here. The success of the tactics of each deceiver, competing male and predaceous *Photuris* female, depends on the influence the other has had, and continues to have on the system. That is, each mimicry provides the basis of support (model) for the other—such reciprocal mimicry is a new phenomenon to science.

The competition flashes (injections) that male *P. macdermotti* inject into the coded dialogues of rivals and contested females are made during the last 0.6 of the rival's flash pattern (Fig. 2b).

Fig. 1 Chart traces of firefly flashes and interactions, recorded with a photomultiplier system during natural and experimentally manipulated interactions in the field and laboratory. Abscissa represents time, measured as a ratio (in the text) with 1.0 being *P. macdermotti* male p_1 - p_2 interval (this removes temperature effects); ordinate, relative intensity. a, *P. macdermotti* male's characteristic two-pulse (that is, p_1 + p_2) flash pattern, and female answer. b, Simulated male pattern with aggressive mimic *P. versicolor* giving false answer. c, Same as b, with *Photuris* 'B' female giving false answer. d, Male flash pattern with rival injection (I); no female response. e, Simulated male pattern with predator *P. versicolor* giving false injection but no false answer. f, Simulated *P. macdermotti* male pattern, with injection (I) by rival male *P. macdermotti* and answer by female. g, Simulated male pattern with aggressive mimic *P. versicolor* emitting both false injection and false answer. h, Same as g, except aggressive mimic *Photuris* 'B' female. i, Various injection forms of competing *P. macdermotti* males. Note similarity to false answers (j) that aggressive mimics give to single, short flashes (see text).

Fig. 2 Time-positioning of various flashed signals and mimics involved in the reciprocal mimicry phenomenon. Abscissa represents time, measured as a fraction of the interval between the two flashes (p_1 and p_2 in Fig. 1) of the *P. macdermotti* male pattern (this corrects for temperature differences among recording sessions as signalling parameters are temperature dependent). The first male flash (p_1) occurs at time 0; the second flash of the male pattern (p_2) occurs at time 1. *a*, Timing of *P. macdermotti* female flash responses, centering ~0.5 units after 1 (p_2). *b*, Timing of *P. macdermotti* male competition flashes (injections). 'Steal' and 'synch' indicate other male tactics³. *c*, Timing of predators' false injections (mimicking *P. macdermotti* male injections, see *b*) and false answers (mimicking *macdermotti* female answers, see *a*). Note the time correspondence between the false injections in *c* and their model in *b* above; and between false answers in *c*, and their model in *a* above. Note particularly that injections and false injections centre ~0.6 units after the preceding male flash (p_1 at time 0), but answers and false answers centre ~0.5 units after the preceding male flash (p_2 at time 1). *d*, Timing of the flashed responses used by predators when answering isolated single (non-paired) flashes—presumably the response given to some as yet undetermined, single-flash prey firefly. Note that this response centres ~0.3 time units after the 'male' stimulus flash that precedes it.

(Decimal fractions are used to indicate time-positioning because the 'clock-time' of these signals varies with temperature. Unity (1.0) is the mean period between the two flashes in the time-coded pattern of flying, searching males².) Injected flashes take various forms. Those discussed here are simple, like those in the normal flash pattern (Fig. 1*i*, asterisk), and occur between 0.5 and 0.8. The timing of these injections is similar to that of the false injections emitted by both *Photuris* predators (Fig. 2*c*). (Injections occurring later than ~0.8 seem to be involved in other competitive, photic tactics; Fig. 2*b*, 'steal' and 'synch'.)

The false injections (male imitation) and the false answers (female imitation) of predaceous females are two different responses, not merely an identical 'pause then flash' response given after different flashes of the two-flash male pattern. That is, the predators do not simply adopt the same response, but use two different pauses (that is, each matching its own model). Note that false injections (Fig. 2*c*) are centred at ~0.6 time units after the male flash that precedes them (p_1 is at 0), and false answers centre at 0.5 time units after the male flash that precedes them (p_2 is at 1.0). Note also the difference in timing of the two in the recordings (Fig. 1*g*, *h*).

The stimulus that elicits the two responses in the predators is the two-flash pattern (the species-specific pattern of *P. macdermotti* males). In contrast, if single flashes are presented at long intervals (>5 s), and therefore a *P. macdermotti*-prey sign-stimulus is not seen by the predator, a different response (pause time) is evoked—this is probably used to prey on another species. In both *P. versicolor* and 'B' this consists of a very short pause, and a modulated flash that is longer than those given in response to *P. macdermotti* patterns (Figs 1*j*, 2*d*). This demonstrates that the false injection is not merely a misplaced false-answer that is correctly used when preying on males of some single-flash species, and it further supports the conclusion that the false injection is a specifically tuned response.

The success of mimics on both sides (predator and prey) depends on the influence the other has on the system. The false injections of *Photuris* must enhance their attraction of prey

because *P. macdermotti* males use their injections to gain advantage over rivals (J.E.L., in preparation), and selection has favoured males that are not duped, but instead continue approaching with caution. The injections of competing males

Fig. 3 Model of an evolutionary 'arms' race (conflict coevolution) leading to reciprocal mimicry of *P. macdermotti* males and their predators, *Photuris* females. A number of variants and origins are possible.

continue to influence rival behaviour because *Photuris* females continue to use them to prey on males. An individual of either species that abandons its mimicry is at a disadvantage in its own individual reproductive effort, thus natural selection independently maintains both components of this reciprocal mimicry.

Historical interactions that may have led to this dual mimicry (Fig. 3) will be discussed in more detail elsewhere, but a further possible mimicry is worth noting because it relates to the presumptive evolutionary origin of false injections, mistakes sometimes made by predators. About 75% of the injections made by *P. macdermotti* males during competition are double or triple flashes (Fig. 1i), which resemble flashes made by *Photuris* in response to single-flash stimuli (Fig. 1j). Males emit these modulated flashes only during mate competition. Their strong resemblance to flashes made by *Photuris* further suggests a highly refined mimicry system.

The communicative-deceptive transactions of these fireflies, both predators and mate-rivals, are more complex and finely tuned than expected. Similar refinement and subtlety probably exist in the communicative ecology of most insects, particularly in the contexts of female mate assessment and choice, but escape detection and general recognition because of the technical difficulties that their signals, especially chemical ones, present to discovery and analysis. Fireflies, therefore, offer unique opportunities for investigation of insect communication.

Removal of bound calcium from nematocyst contents causes discharge

Roger Lubbock & W. B. Amos

Department of Zoology, University of Cambridge, Downing Street, Cambridge CB2 3EJ, UK

Nematocysts are the stinging organelles of jellyfish, sea anemones and other cnidarians. Each one consists of a closed capsule filled with fluid. In the resting state, part of the surface of the capsule is inverted, forming a tubular thread, which is everted explosively on excitation. The mechanism of explosion is not yet understood^{1–3}; it may be relevant to exocytosis in general, as the nematocyst is a specialized type of exocytotic secretion originating in the Golgi apparatus⁴. Picken and Skaer¹ observed that the capsular fluid showed a large depression of freezing point, suggesting that the osmotic pressure might be as high as 140 bar. They tentatively ascribed the explosion to a sudden increase in permeability of the capsule wall, allowing a rapid osmotic influx of water. However, there is evidence that the material of the thread itself may be capable of some degree of extension^{5,6} and it has been suggested that osmosis plays no part in discharge³. We present here a new theory: that the capsule wall is permeable to water even in the undischarged state; discharge is initiated by an increase in the osmotic pressure of the capsular fluid which is brought about by removal of bound calcium ions.

The work was carried out on holotrichous isorhizas from the mesenterial filaments of the coralliomorpharian anemone *Rhodactis rhodostoma*. These nematocysts have the advantage that they are large enough (150 μm long) to be manipulated individually with fine steel needles. All manipulations were carried out in liquid paraffin. Before use, the nematocysts were isolated from the mesenterial filaments by teasing with needles and cleaned of mucus and cell debris by drawing them carefully across a glass surface. Experimental solutions were injected as droplets into the liquid paraffin and the nematocysts transferred from one droplet to the next using a steel needle. Measurements of refractive index were carried out with a Zeiss Jamin–Lebedeff system and with a Baker image-shearing interference system equipped with a fringe-field eyepiece. The freezing point depression of the contents of intact individual capsules was measured by a method to be described in detail elsewhere. It consisted essentially of placing the isolated nematocysts in liquid paraffin inside a sealed chamber which was immersed in a refrigerant of a Ramsay–Brown freezing point apparatus¹. The chamber was viewed microscopically and the formation and melting of ice crystals within individual capsules observed.

This new method of *in situ* measurement revealed slightly higher freezing point depressions than those observed by Picken and Skaer¹, who used nematocysts of *Corynactis* and determined the freezing point of extracted samples of fluid. Our *in situ* measurements on *Rhodactis* gave values for $\Delta^\circ\text{C}$ of -5.4 to -8.2 ($\bar{x} = 6.2$, $n = 15$), whereas those of Picken and Skaer were -4.2 to -5.9 . These values correspond to high notional osmotic pressures, but, as mentioned by Wolf⁷, there is no simple relationship between osmotic pressure and freezing point depression for concentrated macromolecular solutions. Without further knowledge of the chemical composition of the capsular fluid, the osmotic pressure cannot be deduced.

As previously observed⁸, the capsule fluid had a high refractive index. Undischarged capsules gave values as high as 1.378–1.388, corresponding to dry mass concentrations of 25–30% ($n = 4$) in excess over seawater, assuming a refractive increment of 0.0018 (ref. 9). The latter assumption is valid if the capsule solutes are protein, glycoprotein, carbohydrate or amino acids. Capsules which discharged spontaneously underwent a dramatic drop in refractive index over several seconds, which caused the specimens to pass through four orders of interference colour. The final value of refractive index corresponded to a mean dry mass excess over seawater of only 0.56% (s.d. ± 0.16 , $n = 10$) which is probably due to the mass of the capsule wall. It is therefore clear that during discharge there is a massive influx of seawater into the capsule, as observed by others, and that the capsule contents are completely replaced. These observations show that a concentrated and probably highly osmotically active solution in the capsule is drastically diluted during discharge; thus far our findings are consistent with the theory of Picken and Skaer.

Further experiments were performed in an attempt to discover the nature of the process that initiates the influx of water. Attention was directed to calcium because microprobe measurements have shown that the capsule fluid contains calcium at a concentration of about 600 mM per kg wet weight¹⁰. Isolated nematocysts could be made to discharge by placing them in a droplet containing 10 mM potassium citrate¹¹ with 10 mM imidazole buffer, pH 7.0. A similar solution without citrate was ineffective. The excitatory effect was blocked by the addition of 50 mM CaCl_2 to the citrate/imidazole solution (only 1 capsule out of 15 discharged). This blockage was peculiar to calcium, other cations being ineffective: 15 capsules out of 15 discharged in each case when NaCl , KCl or MgCl_2 was used as 50 mM solutions in place of CaCl_2 . The stimulatory effect of citrate is almost certainly due to its chelation of calcium; similar effects were obtained with EGTA. This experiment indicates that calcium ions stabilize the nematocyst in some way (as suggested by Blanquet¹¹) and moreover that their removal may be the cause of discharge.

Table 1 The effects of CaCl_2 and sodium citrate on the tonicity of undischarged capsules

Experiment	No. of shrunken capsules	
	1st solution	2nd solution
CaCl_2 followed by sodium citrate	5	0
CaCl_2 followed by CaCl_2	5	5
Sodium citrate followed by CaCl_2	0	5
Sodium citrate followed by sodium citrate	0	0

In each experiment, groups of five undischarged capsules were placed sequentially for 1 min each in two separate solutions containing 40% w/v polyethylene glycol, 50 mM imidazole buffer, pH 7.0, and either 50 mM CaCl_2 or 50 mM sodium citrate; the state of expansion of the capsules was recorded. A repeat of these experiments with 50 mM MgCl_2 added to the citrate solutions gave similar results. Previously discharged capsules containing only seawater shrank in all the above solutions.

One possibility was that calcium might prevent discharge by rendering the capsule wall impermeable to water. To test this hypothesis, undischarged capsules were placed in a series of stain solutions containing 50 mM imidazole buffer, pH 7.0, and 50 mM CaCl_2 . Capsules were found to be impermeable to a 5% solution of blue dextran (molecular weight (MW) 2×10^6) or to 1% Alcian blue (MW 1,265), even when left for several minutes. However, 1% solutions of phenol red (MW 354), sodium fluoresceinate (MW 376) and bromophenol blue (MW 670) were all able to permeate the capsule, reaching approximately the same concentration as outside within 10–20 s; capsules that had been permeated with stain retained their ability to discharge when placed in a buffered 10 mM citrate solution. These results show that the wall of the undischarged capsule is permeable to charged molecules of relatively low molecular weight. It therefore seems likely that very small molecules such as water can diffuse rapidly in and out of the undischarged nematocyst.

We have considered two other possible mechanisms for the action of calcium. One is that the osmotic pressure of the internal fluid is constant and is continuously exerted; discharge is then made possible by a localized weakening of part of the thread or capsule wall, due perhaps to the loss of calcium as a cross-linking agent. This seems unlikely, as the capsule expands briefly before discharge, as previously observed³, indicating an increase in hydrostatic pressure. An alternative mechanism is that the removal of calcium changes the nature of the capsule fluid such that the osmotic pressure increases.

The latter hypothesis was tested by measuring the tonicity of undischarged capsules with and without calcium in the bathing medium. To prevent discharge, it was necessary to use a solute that could not readily penetrate the capsule wall but was of low enough molecular weight to allow an external solution of relatively high osmotic pressure; polyethylene glycol of MW 1,500 was chosen. Undischarged nematocysts were placed in solutions containing 40% w/v polyethylene glycol, 50 mM imidazole buffer, pH 7.0, and either 50 mM CaCl_2 or 50 mM sodium citrate (Table 1). The capsules shrank when placed in the calcium solution, but re-expanded when placed in the citrate solution. In the reverse experiment, capsules placed first in citrate remained expanded, but shrank when transferred to the calcium solution. These results cannot be ascribed to the increase in the osmotic pressure of the bathing medium due to the addition of the calcium salt, as the addition of 50 mM MgCl_2 to the citrate solutions failed to cause shrinkage. Therefore, these experiments strongly suggest that the tonicity of the capsule fluid in the presence of calcium ions is lower than in their absence.

We propose that the isolated capsule is continuously permeable to water and the internal hydrostatic pressure due to osmosis is sufficient to keep it turgid but insufficient to produce discharge. The normal stimulus for discharge is the removal of calcium from the nematocyst fluid, presumably in ionic form. This results in an increase in the osmotic pressure of the fluid.

The molecular basis of this process is not yet clear; it could involve the dissociation of a macromolecule, creating a larger number of osmotically active particles.

Immunoradiometric assay of human leukocyte interferon using monoclonal antibody

D. S. Secher

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

Interferon research has been hampered by problems in its assay. The only widespread assays use tissue culture cells and compare some parameter of viral growth (such as viral RNA synthesis or host cell death) in the presence and absence of interferon¹. These complex biological assays, though sensitive, are laborious and subject to inherent variability. In particular, components other than interferon present in the assay sample often influence viral growth. There is clearly a need for a simple, direct, interferon assay; I now describe such an assay—an immunoradiometric assay utilizing monoclonal antibody.

The isolation and properties of a monoclonal antibody (NK2) specific for human leukocyte interferon (Hu-IFN α) were recently reported². This antibody was used to purify Hu-IFN α by immuno-adsorption chromatography. The use of labelled antibody (immunoradiometric assay) rather than labelled antigen (radioimmunoassay) may offer improved assay sensitivity for the reasons given by Miles and Hales³ for insulin assay. Monoclonal antibodies are much more easily purified than are monospecific antibodies from conventional antisera and so will allow the widespread exploitation of the advantages of immunoradiometric assays. For this reason, it was of interest to develop a labelled antibody sandwich assay, in which a sheep anti-interferon antibody⁴ is attached to polystyrene and serves to anchor the interferon present in the sample to the solid phase. The bound interferon is then detected by the addition of ¹²⁵I-labelled NK2 (monoclonal anti-Hu-IFN α) and measurement of the counts bound to the solid phase.

Three forms of polystyrene were used as the solid phase: (1) 3-ml test tubes (LP3, Luckham); (2) 96-well microtitre trays (M24, Gibco); and (3) 6.5-mm beads (Northumbria Biologicals). In the first case the whole tube was counted to measure the bound ¹²⁵I-NK2. When trays were used the bottom of each well was cut off with a hot wire and transferred to a clean tube for counting. In the third case the beads were incubated in 20- or 60-well trays (93-0402, 93-0340, Abbott) and transferred to tubes for counting. The incubation volumes used were 1 ml or 0.1 ml (tubes), 0.1 ml (wells) and 0.2 ml (beads). All three supports were satisfactory and for assaying large numbers of samples the beads were preferred for their convenience.

NK2 antibody was purified from the serum and ascites fluid of mice carrying NK2 tumours by ammonium sulphate precipitation and DEAE-ion-exchange chromatography, labelled by the chloramine-T method and desalted on a Sephadex G-50

(fine) column. The labelled IgG had a specific activity of about $2 \text{ Ci } \mu\text{mol}^{-1}$ or about 1 atom ^{125}I per molecule IgG.

In each assay a standard curve was constructed using either the interferon reference standard MRC 69/19 or a laboratory standard. Such a curve is shown in Fig. 1. The counts bound at $8,000 \text{ U ml}^{-1}$ were at a maximum; no further increase was observed with interferon concentrations up to 10^6 U ml^{-1} . The low level of nonspecific binding ($<1\%$) of input counts is an important characteristic of the sandwich assay.

The assay conditions (Fig. 1 legend) were chosen for the convenient measurement of samples encountered in the purification of interferon, with concentrations of $\sim 10^3$ – 10^7 U ml^{-1} . Solutions containing $>10^3 \text{ U ml}^{-1}$ are diluted by serial dilution and the titration curve obtained matched to the standard curve.

Fig. 1 Standard curve for measurement of interferon concentration by immunoradiometric assay (as obtained by J. Walker). IgG was purified from a sheep anti-Hu-IFN α antiserum⁴ (450,000 neutralizing units per ml) by ammonium sulphate precipitation and DEAE-cellulose ion-exchange chromatography and coated on polystyrene beads by incubation of the beads at 4°C for 16 h in the sheep IgG ($20 \mu\text{g ml}^{-1}$ in PBS, 5 mM EDTA, 0.1% NaN_3). Several hundred beads were coated, washed in PBS, 10% horse serum (Sera-Lab), 0.1% NaN_3 (HS medium) and stored in HS medium at 4°C . Assay trays (20- or 60-well, Abbott) were incubated with HS medium at 4°C to block any sites for protein attachment. Interferon samples were diluted in HS medium and duplicate samples ($200 \mu\text{l}$) added to antibody-coated beads (1 bead per well). After 4 h at 4°C the beads were washed with 12 ml HS medium each using a combined dispenser/aspirator (Pentawash, Abbott). After removal of any residual medium, ^{125}I -NK2 (purified IgG, 40,000 c.p.m.) was added and incubated for 16 h at 4°C . The beads were washed as before and transferred to a γ -counter. The dotted line indicates the background c.p.m. bound when the coated beads were incubated in HS medium without interferon. The IFN concentration is expressed in Reference Research Units (RRU) per ml using the MRC standard 69/19 (National Institute for Biological Standards and Control).

The immunoradiometric assay offers considerable advantages over the conventional biological assays. Since the antibody-coated polystyrene can be stored at 4°C , samples can be assayed at short notice and the results are obtained within 24 h of beginning the assay. The reproducibility, between assays, of the immunoradiometric assay is much better than that of biological assays; four measurements of a solution of $2,000 \text{ U ml}^{-1}$ gave a value of $3,063 \pm 345$ c.p.m. in independent assays in which the input c.p.m. was 47,000–53,000 c.p.m. Only small amounts of sheep antibody are used, since the IgG solution used to coat the polystyrene can be used several times without apparently reducing the sensitivity of the assay. The quality of the sheep antibody may not be a critical factor in the success of the assay,

Fig. 2 Standard curve for low levels of interferon. Interferon samples were prepared by dilution of the reference research standard in HS medium and assayed as in Fig. 1 legend except that only 23,000 c.p.m. ^{125}I -NK2 was added to each bead. The dotted line indicates the background c.p.m. bound and was the mean of eight values (s.e.m. = ± 6 c.p.m.).

and other antibodies to Hu-IFN α could probably be substituted. The assay exploits the specificity of the monoclonal antibody NK2, and because this is the product of a hybrid myeloma cell line in culture it can be produced in large amounts without any change in quality. Finally the assay is inexpensive (especially since all the plastic ware except the beads may be re-used), lends itself to automation and several hundred samples can be assayed by one person in a day. Antiviral assays will still be needed to detect any interferons that do not possess the NK2 antigenic site (including IFN β (ref. 5) and possibly some members of the IFN α family) and to confirm biological activity in antigenically positive molecules.

For the measurement of interferon in biological fluids an assay must be capable of detecting much lower levels of interferon than those encountered in production and purification. Figure 2 shows that at low interferon concentrations the counts bound are proportional to the interferon concentration, and concentrations of $\geq 50 \text{ U ml}^{-1}$ can be reliably measured.

Fig. 3 Interferon assay in the presence of human serum. LP3 tubes were coated with sheep anti-interferon ($100 \mu\text{l}$ per tube, conditions as in Fig. 1 legend). Lymphoblastoid interferon (from stock of 10^5 U ml^{-1}) was diluted in HS medium (●) or undiluted normal human serum (○) and $100 \mu\text{l}$ samples assayed in duplicate by incubating at 4°C for 4 h, washing with $3 \times 2 \text{ ml}$ HS medium and then incubating for a further 16 h at 4°C in the presence of 35,000 c.p.m. ^{125}I -NK2 IgG ($100 \mu\text{l}$). After washing again the tubes were counted for radioactivity.

A limitation in the conventional assay of interferon in serum or other biological fluids has been the need to dilute the sample until the effects of other non-interferon substances that affect viral growth no longer mask the action of the interferon. Dilution of a sample of lymphoblastoid interferon in either phosphate-buffered saline (PBS), 10% horse serum, 0.1% NaN_3 or in undiluted normal human serum resulted in identical titration curves (Fig. 3), indicating that the immunoradiometric assay overcomes this problem.

The lower limit in the measurement of serum interferon by biological assays has been sufficient to detect interferon in the serum of some patients with acute viral infections and in the serum of patients to whom interferon has been administered. This sensitivity is insufficient, however, to measure the interferon (if any) in normal human serum.

It should be possible to improve the sensitivity of the immunoradiometric assay still further by optimizing the conditions at low interferon concentrations. In any case the sensitivity of the assay can be further increased by prior concentration and purification of the interferon on a small NK2-affinity column.

I thank Dr K. Cantell for sheep anti-interferon antiserum, Dr Cantell and Professor D. C. Burke for gifts of interferon and for critical discussions, Drs J. Nagington and J. Walker for collaborative studies to be published separately and for introducing me to the coated bead system of radioimmunoassay, Dr C. Milstein for suggestions and encouragement, and R. E. Hawkins and L. T. Davies for technical assistance.

Evidence that the serological determinant of H-Y antigen is carbohydrate

Mark Shapiro & Robert P. Erickson

Department of Human Genetics, Box 015, University of Michigan Medical School, 1137 E. Catherine Street, Ann Arbor, Michigan 48109, USA

The histocompatibility-Y (H-Y) antigen is a minor histocompatibility antigen which has been detected on cell surfaces from the heterogametic sexes of mammalian, bird, amphibian, teleost and invertebrate species¹⁻³. H-Y is thought to be a male-determining substance in mammals because of its almost perfect correlation with maleness among a variety of mammalian species. To characterize the molecular determinant responsible for H-Y-specific serological activity, H-Y-positive immunoabsorbent cells were first subjected to various treatments which alter protein or carbohydrate structure and then tested for their ability to absorb H-Y antisera. We present here evidence that the serological determinant of H-Y antigen is carbohydrate.

To assess the dependence of H-Y serological activity on polypeptide structure, absorbing cells were treated with the proteases trypsin, α -chymotrypsin and thermolysin. After enzyme treatment and washing, treated splenocytes were used to absorb an aliquot of H-Y antiserum. In this and all subsequent experiments, absorbed sera were tested for cytotoxic activity against male murine epidermal cells. Splenocytes treated with either trypsin, α -chymotrypsin or thermolysin

showed almost the same absorptive capacities as untreated splenocytes (Fig. 1). These results indicate that H-Y-specific serological activity is resistant to these three proteolytic enzyme treatments.

To determine the dependence of H-Y serological activity on carbohydrates, absorbing cells were treated with periodate, which oxidizes 1,2-dihydroxyethyl linkages found in glycosyl residues. Splenocytes were treated with varying concentrations of periodate and washed in a protein+sugar-supplemented medium before absorption. Sensitivity of H-Y-specific absorption to periodate treatment, as well as subsequent experimental treatments, were quantified as corrected per cent inhibition of absorption, as defined in Fig. 2 legend. As a control, the same treatments were performed on absorbing cells bearing antigens of the H-2^b haplotype. Such serological determinants are thought to be contained in amino acid sequences^{4,5}. These data show H-Y-specific absorption to be ~ fivefold more periodate sensitive than H-2 (Fig. 2a).

A more direct assessment of the carbohydrate dependence of H-Y serological activity can be made by treating absorbing cells

Fig. 1 H-Y-specific absorption: resistance to proteolytic enzymes. Purified trypsin (Gibco), α -chymotrypsin (Worthington), and thermolysin (Calbiochem) were dissolved in Puck's saline F (PSF) to yield individual suspensions containing 0.1% enzyme by weight. Samples containing 4×10^7 splenocytes were incubated in a 2-ml enzyme suspension at pH 7.4, 37°C for 20 min, washed three times at 4°C in Medium 199 containing 10% heat-inactivated (56°C, 30 min) γ -globulin-free fetal calf serum (FCS, Gibco) and used to absorb 25- μ l aliquots of rat H-Y antiserum diluted 1:4 in Medium 199 containing 10% FCS. Rat H-Y antiserum was prepared by the method of Fellous *et al.*⁹ by immunizing female Fisher rats with male (Fisher) splenocytes. Before use in this experiment, rat antisera were heat inactivated (56°C, 30 min) and absorbed with equal volumes of female murine splenocytes for 1 h at both 0 and 37°C. An antiserum was regarded as H-Y specific if it had cytotoxic activity against male, but not female, C57BL/6J (B6) epidermal cells, and this activity could be absorbed by male, but not female B6 splenocytes. H-Y-specific immunoabsorption was done on ice (~0°C) for 1 h. Absorbed sera were tested for direct cytotoxicity against B6 epidermal cells according to the method of Scheid *et al.*¹⁰ with the exception that heat-inactivated γ -globulin-free FCS was used as a protein supplement for the isolation medium. Cell killing was quantified by the cytotoxic index, *i*, defined as: no. dead cells in sample - no. cells killed by complement dose/total no. cells - no. cells killed by complement alone.

with exo-glycosylhydrolases which remove a terminal glycosyl residue from the non-reducing end of a carbohydrate chain. Splenocytes were treated with highly purified β -glucuronidase and β -galactosidase, then washed in protein-enriched media before absorption. Figure 2b shows a graph of corrected per cent inhibition of absorption versus units of enzyme used for treatment. Whereas H-Y-specific absorption is resistant to β -glucuronidase treatment (1,000 units of enzyme destroy 2% of activity from the absorbing cells), it is sensitive to β -galactosidase to the extent that 1,000 units of enzyme remove 54% of the H-Y absorptive capacity of male mouse splenocytes. To confirm that the inhibition by β -galactosidase is not due to uptake of the enzyme by the absorbing cells, the 1,000-unit enzyme treatment was repeated for H-Y in the presence of 0.1 M mannose-6-phosphate, which inhibits the uptake of β -galactosidase by mammalian cells. In the presence of mannose-6-phosphate, the 1,000-unit β -galactosidase treatment still destroyed 45% of H-Y-specific absorptive activity (Table 1). As another control, the 1,000-unit β -galactosidase treatment was used on absorbing cells specific for H-2^b antigens. H-2^b-specific

absorption is completely insensitive to the action of 1,000 units of β -galactosidase (Table 1).

These data suggest that the integrity of an H-Y serological determinant is perturbed by the removal of a terminal galactose from the non-reducing end of an associated carbohydrate moiety. To test further the serological dependence of H-Y on a non-reducing terminal galactose residue, we performed a series of absorbing cell treatments using galactose oxidase, which oxidizes the terminal galactose residue at the non-reducing ends of a carbohydrate chain. Although galactose oxidase has no appreciable effect on H-2^b-specific absorption, it inhibits H-Y-specific absorption by male mouse splenocytes by as much as 38% in this experiment (Fig. 2c).

To verify that the inhibition of H-Y observed here is due to the specific oxidation of a terminal non-reducing galactose rather than to nonspecific oxidation at the cell surface, a similar experiment was carried out using glucose oxidase. Whereas 10 units of galactose oxidase inhibit H-Y-specific absorption by 38%, an equivalent amount of glucose oxidase had only an 8% inhibitory effect (Table 1). This value could possibly be due to

Fig. 2 Sensitivity of H-Y-specific absorption to all treatments quantified as corrected per cent inhibition of absorption, defined as:

$$\frac{i(\text{treated cells}) - i(\text{untreated cells})}{i(\text{unabsorbed serum}) - i(\text{untreated cells})}$$

with i defined as in Fig. 1 legend. Each per cent inhibition value represents the mean of duplicate samples. **a**, Known concentrations of periodic acid (Frederick Smith Chemicals) were dissolved in isotonic phosphate buffer and adjusted to pH 7.4. Splenocytes were treated at a concentration of 10^7 cells per ml (10^7 total cells for H-2 and 2×10^7 total cells for H-Y) for 10 min at room temperature ($\sim 22^\circ\text{C}$). After treatment, the cells were washed twice in Medium 199 containing 10% FCS at 4°C . Treated splenocytes were used to absorb either mouse H-Y (diluted 1:4) or H-2^b antiserum (diluted 1:100) as described in Fig. 1 legend. Mouse H-Y antiserum was prepared as described by Krco and Goldberg⁴. H-2^b antiserum was an equivolume mixture of alloantisera to murine H-2.2(D-2) and H-2.33(D-33) specificities obtained from the NIH. Absorbed H-Y antiserum was tested for cytotoxicity as described above. H-2^b antisera were tested for direct cytotoxicity against splenocytes in the following way. Equal amounts (10 μl) of H-2^b antiserum and B6 splenocytes (8×10^6 per ml) were incubated for 20 min at room temperature; 10 μl of baby rabbit complement (Pel Freez) diluted 1:4 was then added and the suspension incubated at 37°C for 35 min. Trypan blue (10 μl of 0.2% dye) was added for the final 5 min of incubation to stain dead splenocytes. Formalin saline (10 μl containing 5% formaldehyde) was added as a fixative and live and dead cells were counted. $\circ$, H-2^b; Δ , H-Y. **b**, Highly purified rat β -glucuronidase ($\circ$) and bovine β -galactosidase (Δ) (both 12,000 units per mg protein) were obtained from Dr Virginia Hieber, Department of Pediatrics and Communicable Diseases, University of Michigan Medical School. Splenocytes (2×10^7 total) were treated with known amounts of enzyme in 2.0 ml incubation volumes containing phosphate buffered saline (PBS) at pH 6.8, 37°C for 1 h. After treatment, cells were washed twice in Medium 199 containing 10% FCS at 4°C before absorption. Antisera used for absorption and subsequent cytotoxicity testing were murine H-2^b and rat H-Y antisera as described above. **c**, Galactose oxidase (Sigma) was dissolved in PBS containing 1.0 mg per ml of bovine serum albumin (BSA, Sigma). Splenocytes were incubated with known amounts of enzyme in PBS, pH 7.4, at 37°C for 1 h. Each incubation mixture contained 10^7 (in the case of H-2^b, $\circ$) or 4×10^7 (in the case of H-Y, Δ) splenocytes plus enzyme at a volume of 0.5 ml. After incubation, treated cells were washed in Medium 199 supplemented with 1.0 M galactose before absorption. Antisera were either murine H-2^b or rat H-Y as described above. Absorption and subsequent cytotoxicity testing were as before.

Table 1 Specificities of enzyme treatment

Enzyme treatment	Total enzyme (U)	% Inhibition of absorption (mean $\pm$ s.e.)	
		H-2 ^b	H-Y
β -Galactosidase alone	1,000	0 $\pm$ 1	54 $\pm$ 8
β -Galactosidase + 0.1 M mannose-6-phosphate	1,000	—	45 $\pm$ 4
Galactose oxidase	10	0 $\pm$ 1	38 $\pm$ 2
Glucose oxidase	10	0 $\pm$ 1	8 $\pm$ 2

β -Galactosidase treatments in the presence of mannose-6-phosphate (Sigma) were as described for Fig. 2b with the exception that 0.1 M mannose-6-phosphate was added to the treatment buffer. Glucose oxidase treatments were as described for Fig. 2c with the exceptions that glucose oxidase (Sigma) was the enzyme used and that treated cells were washed in Medium 199 supplemented with 1.0 M glucose.

the presence of contaminating amounts of galactose oxidase in our enzyme preparation (2% according to manufacturer). In addition, H-2^b was tested for inhibition of absorption by glucose oxidase and no effect was observed (Table 1). These data are consistent with the suggestion that the integrity of an H-Y serological determinant is perturbed by structural alterations directed against a terminal non-reducing galactose on an associated carbohydrate moiety.

The serological reactivity of H-Y antigen, as measured by immunoabsorption, is demonstrated here to be resistant to the action of various proteolytic enzyme treatments. This result implies that the H-Y serological determinant is not a protein, or that it is part of a polypeptide chain resistant to proteolysis. The resistance to proteolysis of H-Y, in combination with its greater sensitivity to periodate than H-2 suggest that the H-Y-specific serological determinant is more likely to be carbohydrate than protein. In most of the experiments reported here, H-2 is used as a control as it is a well characterized glycoprotein antigen whose serological activity is resistant to treatments directed at carbohydrate structures, but sensitive to protein-directed treatments^{5,6}.

We have reported that H-Y-specific absorption is sensitive to both β -galactosidase and galactose oxidase treatments. The sensitivity of H-Y-specific absorption to both these enzymes is in the range 29–54%. Although these values do not reflect complete inhibition, they are consistent with the accepted model of antigen-antibody interaction involving binding of the combining site of an antibody molecule with a carbohydrate determinant of 4–6 glycosyl residues⁷. By perturbing a terminal galactose residue on such a carbohydrate determinant, one would expect detectable, although not complete, inhibition of antibody binding. Thus, our observations of β -galactosidase and galactose oxidase sensitivity indicate a role for a terminal non-reducing galactose residue in the serological integrity of H-Y antigen.

If the serologically active portion of H-Y is carbohydrate, this could account for its evolutionary conservation, suggested by the broad serological cross-reactivity of H-Y-like substances from a variety of species^{1,2,8}. A carbohydrate nature for this determinant could also explain why antisera raised against it are of low titre (1:16–1:32 in the case of our antisera) and affinity. Although the results reported here suggest a carbohydrate nature for the H-Y serological determinant, direct demonstration of whether this immunological determinant is itself a carbohydrate, or is strictly dependent on a carbohydrate chain requires further experimentation.

This work was presented at the meeting of the American Society for Cell Biology in Cincinnati, Ohio on 14–18 November 1980. The abstract of this presentation is published elsewhere⁸.

We thank Dr Virginia Hieber for her gift of purified β -glucuronidase and β -galactosidase and Mrs Rena Jones for secretarial assistance. This work was supported by grant HD 11738 and predoctoral training grant GM 7544 from the NIH.

Fibrinolysis with acyl-enzymes: a new approach to thrombolytic therapy

R. A. G. Smith, R. J. Dupe, P. D. English & J. Green

Beecham Pharmaceuticals Research Division, Biosciences Research Centre, Great Burgh, Yew Tree Bottom Road, Epsom, Surrey KT18 5XQ, UK

Deep vein thrombosis in man presents a considerable clinical challenge. Despite the availability of prophylactic measures, therapeutic thrombolysis is often necessary, but is difficult and hazardous. Treatments have included the administration of plasmin, other less specific proteolytic enzymes, the indirect plasminogen activator, streptokinase, and the direct activators, urokinase and streptokinase-human plasmin complex. All these treatments have been associated with some haemostatic breakdown, which has discouraged their widespread application. The enzyme components of the coagulation and fibrinolytic pathways can, in general, be classed as serine proteases¹, with a catalytic mechanism which operates via acyl-enzyme intermediates². Chase and Shaw³ showed that *p*-nitrophenyl-*p*'-guanidinobenzoate could specifically acylate the active centre of trypsin-like enzymes, giving rise to a stable *p*-guanidinobenzoyl enzyme and other stable acyl-enzymes have since been described^{4,5}. We report here the fibrinolytic use of acylated derivatives of plasmin (E.C.3.4.21.7) and streptokinase-plasmin(ogen) complexes.

An acyl-plasmin, catalytically inert and therefore unable either to degrade systemic plasma proteins or react irreversibly with its principal plasma inhibitors (α 2-antiplasmin^{6,7} and α 2-macroglobulin⁸), may still bind to a fibrin clot because the lysine/fibrin binding sites on the 'kringle' domains of plasmin are structurally and functionally separate from the catalytic centre⁹ (Fig. 1). Deacylation may then occur to give fibrin-bound plasmin. Wiman and Collen¹⁰ have shown that the involvement of the lysine binding sites of plasmin in binding to fibrin reduces the effectiveness of α 2-antiplasmin and provides part of the molecular basis for selective fibrinolysis *in vivo*¹¹. Thus, if an acyl-plasmin is administered to an animal, the release of plasmin by deacylation of fibrin-bound acyl-plasmin would be expected (within certain kinetic limits) to lead to fibrinolysis. In the systemic circulation, however, α 2-antiplasmin would be expected to act rapidly to neutralize the plasmin released by deacylation, provided that the rate and dose were not so great as to consume the α 2-antiplasmin content of the plasma. The concept of active centre acylation may also be applied to plasminogen activators, provided that they too possess fibrin affinity independent of the catalytic centre. In that case, acylation would allow the activator to reduce interactions with plasma plasminogen which lead, during current therapy in man, to harmful plasminemia¹². The putative advantages of therapeutic thrombolysis with acyl-plasmins and acyl-activators, therefore, are (1) enhanced efficacy, due to evasion of inhibitor systems; (2) sustained-release pharmacokinetics, leading to simplified administration and easier clinical control; (3) reduction of

systemic toxicity attributable to hyperplasmaemia; and (4) protection of the enzymes against autolytic degradation.

A general method for the specific synthesis of acyl-enzymes was developed using *p*-aminodiphenyl esters which function as 'inverse' acylating agents¹³. Acyl group radiolabelling demonstrated that active-site acylation with these reagents was quantitative in conditions where nonspecific protein modification was negligible. We prepared acyl derivatives of both human and porcine plasmins, streptokinase-human plasmin activator complex¹⁴ and urokinase, and studied their deacylation rates¹⁵. Using *p*-³H-methoxybenzoyl human plasmin, we found that plasma components on fibrin did not affect the deacylation rate of the acyl-enzyme, and we have confirmed (using immobilized fibrin monomer¹⁶) that active site acylation of plasmin did not affect its affinity for fibrin. Experiments in which *p*-anisoyl human plasmin was mixed with partially purified human $\alpha 2$ -antiplasmin⁷, incubated, re-isolated by affinity absorption on L-lysine-Sepharose¹⁷ and deacylated, showed that an acyl-plasmin did not react irreversibly with the inhibitor. Also, delayed-action fibrinolysis could be demonstrated *in vitro* by incubating human plasma clots with acyl-plasmin, washing and reincubating for a sufficient time to allow deacylation of the absorbed enzyme. Net lysis with acyl-enzymes was significantly greater than lysis by unmodified plasmins.

The kinetics of $\alpha 2$ -antiplasmin action are sufficiently understood¹⁰ to allow the calculation of the steady-state concentrations of free plasmin corresponding to a given rate of deacylation and a given level of acyl-enzyme. Our experimental data in animals have indicated that a steady-state plasma concentration of plasmin amidolytic activity above ~ 10 nM is associated with fibrinogen depletion. It is possible to calculate the relationship between the deacylation rate and dose of an acyl-plasmin that would be consistent with lack of fibrinogen depletion *in vivo*. An acyl-plasmin, at a single dose that would give an initial plasma concentration somewhat less than the known concentration of $\alpha 2$ -antiplasmin in human plasma ($\sim 0.7 \mu\text{M}$)¹⁰, would require a

Fig. 2 Release of ^{125}I -fibrin degradation products into the bloodstream of rabbits treated with acylated (▲) and free (■) human plasmins and 0.9% saline solution (●). ^{125}I -fibrin thrombi were prepared in the inferior vena cava of rabbits as detailed elsewhere¹⁵ with the modification that a single strand of 4-ply wool was inserted into the isolated vein segment before thrombus formation to act as a clot anchor. Human plasmin (Kabi batch DtB 23 and Choay batch P299 Pm) was assayed using active site titration³ and amidolytic activity²⁰, and dialysed against 20% v/v glycerol, 0.9% w/v NaCl at 4 °C for 2 h before administration at a dose of 10 mg active enzyme per kg in ~ 20 ml, by constant infusion over 2 h. BRL 26920 was prepared in solution from the above plasmins and 1.0 mM *p*-aminodiphenyl-*p'*-anisate. HCl at 4 °C, pH 7.4 for 1 h, followed by dialysis as above. Complete acylation was checked by amidolytic assay²⁰ and administration was by infusion over 5 min. Control saline, 0.9% w/v, was given over 2 h. ^{125}I -FDP in blood samples was determined by well scintillation counting in a manual bioscint γ counter (Panax) and is given as mean ($\pm$ s.e.m.) concentrations for 12 (BRL 26920), 7 (free plasmin) and 8 (control) animals. Final lysis figures are given in Table 1.

Fig. 1 Schematic outline of the mechanism of fibrinolysis by acyl-plasmins. For description see text. Polypeptide chain structure of plasmin was adapted from ref. 9.

deacylation rate constant of $< 1.0 \times 10^{-3} \text{ s}^{-1}$ if the steady-state level of systemic plasmin were to be kept below 10 nM. One can apply kinetic data on the plasmin- $\alpha 2$ -antiplasmin reaction¹⁸ to a calculation of the steady-state concentration of fibrin-bound plasmin necessary to sustain fibrinolysis in the presence of $\alpha 2$ -antiplasmin, using reasonable estimates of the apparent first-order rate constant for breakage of a single peptide bond in the fibrin-plasmin complex, and an estimate of the number of peptide bonds whose cleavage suffices to detach one fibrin monomer from polymeric fibrin¹⁹. Calculation then suggests that a steady-state fibrin-bound plasmin concentration > 0.1 nM may be necessary to achieve clot breakdown within a few hours. Acyl-plasmins given at a dose of ~ 0.5 – $1.0 \mu\text{M}$ should achieve this steady-state situation if their deacylation rate constants are greater than $\sim 10^{-5} \text{ s}^{-1}$. Acyl-plasminogen activators require a more complex analysis to take into account the relative rates of activation of plasma and fibrin-bound plasminogen. Control of fibrinolysis *in vivo* by manipulation of acyl-activator deacylation rates could be expected to be correspondingly more difficult, depending in practice on factors such as the plasminogen content of the fibrin clot, and the breakdown and clearance mechanism for both acylated and free activator. After analysis of the steady-state kinetics we concluded that deacylation rate constants of $\sim 10^{-4} \text{ s}^{-1}$ should be consistent with thrombolytic activity for both classes of fibrinolytic agent. Two such agents, *p*-anisoyl human plasmin (BRL 26920), with a deacylation half life of 96 min, and a *p*-anisoyl human plasminogen-streptokinase activator (BRL 26921), with a deacylation half life of 40 min (both measured at 37 °C, pH 7.4), have been selected for further evaluation.

We studied the effects of the two agents compared with saline controls, human plasmin and various streptokinase-plasmin complexes in models of venous thrombosis in the rabbit and the

beagle dog (to be published, but partly described elsewhere¹⁵). In both models thromboplastin-induced venous clots radiolabelled with human ¹²⁵I-fibrin were formed around an implanted woollen thread anchored into a major vessel. Lysis was studied by release of ¹²⁵I-fibrin degradation products (¹²⁵I-FDP) into the circulation and by measurement of clot radioactivity at the end of the experiments.

In the rabbit model, acyl-plasmins caused significant thrombolysis when given intravenously as single boluses. Figure 2 shows the effect in rabbits of 10 mg per kg of activator-free free human plasmin (infused over 2 h due to its acute toxicity) and the equivalent bolus dose of BRL 26920, compared with controls given saline. The free plasmin and saline groups showed no significant release of radiolabel into the circulation and gave low, not significantly different, end lysis figures (Table 1). The BRL 26920 group showed sustained release of radioactivity over 5 h and significant net thrombolysis. Free plasmin depleted fibrinogen almost completely, whereas BRL 26920 showed significantly less fibrinogenolysis (Table 1). Plasmin amidolytic activity (chromogenic substrate assay²⁰) in the plasma of animals treated with plasmin was much greater than in animals treated with BRL 26920. The thrombolytic activity of BRL 26920 was also observed in dogs (Table 1).

Because of the known species differences in the mechanism of thrombolysis by streptokinase^{21,22}, BRL 26921 was compared in animals with non-acylated streptokinase-plasmin activator complexes prepared in various conditions (Table 1). Of the unmodified activators, only the minimally degraded form (Type 2) showed significant thrombolytic activity. When degraded activator (Type 1) was *p*-anisoylated at the active centre, the acyl-activator showed increased thrombolytic activity at the equivalent dose. BRL 26921 was tested in groups of rabbits at

three dose levels (Table 1) and showed significant thrombolysis compared with the saline controls. At 2,500 units per kg, all BRL 26921 preparations were consistently more active than all non-acylated activator preparations ($P < 0.01$) and a significant slowing in the rate of ¹²⁵I-FDP release was observed when animals that responded to non-acylated activators were compared with those given acylated activators. None of the tested agents significantly altered fibrinogen levels in the rabbits.

BRL 26921 also showed highly significant thrombolytic activity (measured radiochemically and venographically) against freshly formed thrombi in dogs at two dose levels when compared with saline controls and the least degraded activator form (Table 1). A sustained release of ¹²⁵I-FDP over 4–5 h followed a single dose of BRL 26921. In another group of dogs, the thrombi were aged by isolation from the circulation for 24 h. Isolating ligatures were removed and the dogs treated with BRL 26921 at a single dose of 5,000 units per kg. Radiochemical measurements and venography indicated good thrombolysis (Table 1).

We believe that acyl-enzymes are a novel class of therapeutic agents, in which suitable acyl group modification can provide enzyme precursors whose properties can be manipulated to suit various clinical situations, depending on whether fast or slow thrombolysis is required. Because of their novel pharmacokinetics *in vivo*, they could be expected to show advantages over currently used thrombolytic agents, particularly in producing reduced hyperplasmaemia. We consider that BRL 26921 (which is the more active and accessible agent) may lead to useful improvements in the management of venous thrombosis and some types of arterial thromboembolic disease²³.

We thank Dr J. Cash for advice and help over several years, and also Kabi (Stockholm), Choay (Paris), Novo (Copenhagen)

Table 1 Summary of thrombolytic action of agents in rabbit and dog models of venous thrombosis

Model	Agent	Dose SK units (mg) per kg	No. of animals	% Lysis	% Fibrinogen level	Time to peak ¹²⁵ I-FDP levels (min)
Rabbit	Saline	—	8	3 ± 1	110 ± 1	—
Rabbit	Free human plasmin	(10)	7	7 ± 1	4 ± 3	—
Rabbit	SK-Pm activator Type 1	2,500	5	5 ± 1	95 ± 1	—
Rabbit	SK-Pm activator Type 2	2,500	6	20 ± 4	106 ± 3	49 ± 8

Dog (short-term)	BRL 26920	(10)	5	65 ± 9	91 ± 2	330 ± 13
Dog (long-term)	Saline	—	5	38 ± 7	100 ± 7	—
Dog (long-term)	BRL 26921	5,000	5	98 ± 2	100 ± 8	276 ± 78

Activator complexes were prepared from equimolar proportions of streptokinase (SK, Kabi) and lys-plasminogen (Pm, Kabi, K 2086) at a total protein concentration of 1 mg ml⁻¹ in 0.1 M Tris-HCl, 0.9% w/v NaCl, 20% v/v glycerol, pH 7.4. Type 1 activator (degraded) was prepared at 25 °C for 40 min, Type 2 activator (minimally degraded) at 0 °C for 10 min; Type 3 activator was a commercial lyophilized preparation (Behringwerke, Lot 9018) and was dissolved in 0.9% w/v NaCl at a concentration of 1.4 × 10⁵ U ml⁻¹. Acylation of activator complexes was carried out using 1.0 mM *p*-amidinophenyl *p*'-anisate. HCl at 0 °C for 1 h. Other conditions as above. BRL 26921 was prepared in solution by addition of acylating agent to streptokinase, followed by addition of plasminogen and reaction at 0 °C for 1 h. Lyophilized BRL 26921 was prepared on a large scale in solution, diafiltered exhaustively to remove excess acylating agent and lyophilized in the presence of L-lysine, HCl, D-mannitol and human serum albumin. Doses were based on streptokinase contents of activator complexes and administered in 2.0 ml of 0.9% w/v NaCl as a single bolus over 2 min. For plasmin and BRL 26920 dosage and preparation, see Fig. 2 legend. Fibrinogen level was estimated by a modification of the spectrophotometric method of Burmester *et al.*²⁴ at 280 nm. Percentages of the initial level averaged over the experimental period (5 h for rabbits, 6 h for short-term dogs) and over the experimental group. % Lysis, % fibrinogen level and time to peak ¹²⁵I-FDP levels are all means (±s.e.m.). For rabbit model see ref. 15 and Fig. 2. The short-term dog model was similar in outline to the rabbit model, except that thrombi were located in a section of the femoral vein. Homogeneous radiolabelling of blood before clotting around a woollen thread was achieved by aspirating the blood within an isolated vein segment through a collateral vein into a syringe containing radiolabelled fibrinogen. Blood was then returned to the evacuated segment which had been injected with rabbit brain thromboplastin, and restricting ligatures removed after clotting. In the long-term modification of the dog model, restricting ligatures were kept in place to isolate the thrombus from the circulation for 24 h. Treatment was initiated after removal of the ligatures.

and Behringwerke (Marburg) for generous gifts of materials. We also thank Mr I. Dodd, Mr C. Beilby, Miss H. C. Grundy and, in particular, Mr M. J. Hibbs for technical assistance.

Supposed lamarckian inheritance of immunological tolerance

L. Brent*, L. S. Rayfield*, P. Chandler†, W. Fierz†, P. B. Medawar† & E. Simpson†

The notion that an adaptation acquired during an organism's lifetime can somehow be imprinted on the genome and so become heritable has been faulted by every critical test to which it has hitherto been exposed, but many naturalists have lost their faith in what seems to them to be the all-encompassing explanatory glibness of neo-darwinism. Although this criticism is unfair it is entirely proper that neo-darwinism should be under constant critical scrutiny. Interest was therefore aroused by the claim of Gorczynski and Steele¹ that tolerance of A strain antigens induced in CBA mice by injecting into them (CBA × A/J)F₁ spleen and bone marrow cells could be transmitted down the male line. Such a claim is of particular interest because spermatozoa, unlike oocytes, are produced throughout life and might thus conceivably have participated in the mechanism envisaged by Steele² as that responsible for the supposed transfer of genetic information from soma to germ plasm. It was claimed that as many as 60% of the progeny of tolerant fathers mated with normal CBA females were unresponsive or hyporesponsive in an *in vitro* assay in which their spleen cells were tested for reactivity against A/J strain histocompatibility antigens in the cell-mediated lympholysis assay (CML). We describe here our failure to confirm these findings and our inability to extend them by testing the progeny for their reactivity against skin allografts from the tolerance-conferring strain.

Newborn CBA/Ca (H-2^k) mice (CBA) from six litters were made tolerant of A/J (H-2^d) (A) histocompatibility antigens by the intraperitoneal inoculation of 5×10^7 adult male (CBA × A)F₁ hybrid lymphoid cells, consisting of a 1:10 mixture of bone

marrow and spleen cells. Ten males received the same dose of spleen cells every 2 weeks throughout the breeding programme. The remainder, 13 females and 4 males, received skin grafts from male A strain donors 8 weeks after birth: instead of being sloughed off in 10–11 days, grafts were fully accepted and they remain healthy at the time of writing (11 months later). Of the 10 males selected for breeding, 4 (nos 1–4) received A strain skin grafts 1 week after mating; these animals were likewise fully tolerant. The other six males (nos 5–10) did not receive their skin grafts until the completion of breeding 6 months after birth; these too proved to be fully tolerant.

Each tolerant male was mated with three normal CBA females, and the progeny were marked so that each individual was identifiable throughout the experiment, thus making it possible to compare litters from individual fathers in the two assays used (CML and grafting). A similar procedure was followed in the production of progeny from normal CBA fathers. A total of 201 experimental progeny and 138 normal (or control) progeny were raised; the immunological reactivity of the majority was assessed using the CML assay, and almost all received strain A or (CBA × A)F₁ hybrid skin allografts after completion of the *in vitro* tests. Although Gorczynski and Steele had used only splenic lymphocytes for CML testing, peripheral blood lymphocytes (PBLs) were used by us for a large number of mice because this allowed repeated observations with minimal interference and the transplantation of skin grafts to the same animals. Splenic lymphocytes were used in other experiments; these were obtained by removing a small portion of the spleen, thus ensuring that these animals had splenic tissue at the time of skin grafting. About two-thirds of all hemisplenectomized mice had previously been tested at least once using PBLs. The latter were prepared from heparinized blood drawn from a tail vein, hemisplenectomy was carried out under full Sagatal anaesthesia through a small lateral incision, and skin grafting was done according to the technique of Billingham and Medawar³. Skin grafts were first inspected on day 10 or 11 and thereafter scored daily, necrosis of the whole graft surface providing the end point. Although strain A tail skin was used in the earlier experiments, most of the progeny received (CBA × A)F₁ hybrid grafts because it was felt that this might favour longer survival in hyporeactive animals, a point to which Steele drew our attention.

The *in vitro* sensitization and ⁵¹Cr release CML assay were performed on PBLs as described by Chandler *et al.*⁴. Briefly, PBLs were separated from red cells by hypotonic shock and suspended at 1×10^6 per ml in bicarbonate-buffered RPMI medium supplemented with fetal calf serum, 10 mM HEPES, 5×10^{-5} M 2-mercaptoethanol, glutamine, penicillin and streptomycin. Aliquots (100 µl) of this suspension were placed in each well of round-bottomed microtitre plates (Sterilin M24

Fig. 1 Cytotoxic responses of experimental and control fathers (spleen versus PBLs). Cytotoxicity is at a K:T ratio of 5:1, derived from regression analysis.

Fig. 2 Anti-A cytotoxic responses of PBLs (panels a–d) and spleen cells (e–g). A, experimental fathers, also shown in Fig. 1. B, males given only one neonatal inoculation of 5×10^7 (CBA $\times$ A) F_1 spleen and bone marrow cells. C, control fathers. The progeny are identified by the number of the father followed by A or C and then the individual litter number. Each panel represents the data from a separate experiment, with sex of the responders indicated. Cytotoxicity is at a K:T ratio of 5:1, derived from regression analysis.

ART) and the same volume and concentration of irradiated (2,000 rad) allogeneic spleen cells were added as antigen. Three to six wells of each PBL sample were set up against the allo-antigen being tested, A/J, and whenever PBL recovery had been sufficient (in over 70% of samples), a further three to six wells were set up against 'third party' C57BL/10 alloantigen. After 5 days' incubation at 37 °C and in a humidified 5% CO₂ atmosphere, the responder ('killer') cells were collected and the appropriate wells for each sample pooled, counted and dispensed in four twofold dilutions into fresh microtitre plates. 5×10^3 or 1×10^4 ^{51}Cr -labelled 24-h concanavalin A blasts from spleen cultures of A/J or C57BL/10 were then added. The highest killer: target ratio (K:T) was 10:1. The plates were spun briefly and incubated for 3 h before removal of an aliquot of the supernatant for γ -counting. Percentage specific lysis was taken

as $(E - C/M) \times 100$, where E was the c.p.m. for the experimental supernatant, C the c.p.m. for the medium control supernatant and M the c.p.m. of target cells lysed with 5% Triton. Regression analysis of the percentages of specific lysis titrated against K:T ratio was performed and from this curve the percentage of specific lysis at a ratio of 5:1 was obtained. The r^2 value (r = the coefficient of correlation) of each curve was recorded and used in the assessment of the results.

Spleen cells from partial splenectomy were set up in culture in the same RPMI-supplemented medium as the PBLs, but at a concentration of $5 \times 10^6 \text{ ml}^{-1}$. Aliquots (2 ml) of this suspension were incubated in 7-ml Linbro wells (Flow Laboratories 76-053-05) together with 2 ml of irradiated spleen cells ($5 \times 10^6 \text{ ml}^{-1}$) as antigen. The cells were cultured for 5 days and the assay performed as for PBLs, except that the ^{51}Cr -labelled

Table 1 Survival of skin allografts transplanted to experimental and control progeny

† Progeny not tested in CML.

‡ Only tested with PBLs.

§ Tested with PBLs and spleen cells.

target cells were increased to 1×10^5 per well; the highest K:T ratio was again $\sim 10:1$.

Both PBL and spleen samples were scrupulously randomized and coded at the time of their removal from the mice. This code was not broken until after the CML results had been computed.

In most experiments, responders of only one sex were used. Spleen cells from female mice were used for antigen and as targets whenever the responder cell donors were females. Male mice were normally stimulated by, and tested on, male cells but

on a few occasions (and always in experiments where both males and females were used as responders) female antigen and target cells were used. In this way the analysis remained uncomplicated by anti-H-Y reactivity.

The results of testing the tolerant (designated A) and the normal (designated C) fathers in the CML test, using both PBLs and spleen, are shown in Fig. 1 and in Fig. 2, panels 1a and 1e. The two groups are clearly distinguishable from each other by their CML reactivity to A strain, but not to third party B10,

alloantigens. The tolerant CBA fathers were thus specifically hyporesponsive to A strain antigens and this hyporesponsiveness is shown equally by splenic and peripheral blood lymphocytes. Nevertheless, they were considerably more responsive than were the tolerant CBA fathers in Gorczynski and Steele's experiments¹. The reason for this difference cannot be that in our study CML reactivity was tested at a rather late stage (~10 months after birth) because this was also true of the experimental fathers tested by Gorczynski and Steele¹ (8–10 months). It could, however, reflect the fact that the control CBA-anti-A/J response in Gorczynski and Steele's experiments was substantially lower than that in many of our experiments or that, contrary to our practice, their assessment was made with control mice that had not been age-matched. Bearing in mind the advanced age of the experimental fathers, this makes a direct comparison of paternal CML responsiveness in the two studies difficult.

The CML data of the progeny (Fig. 2, panels 2a–3d and 2e–3g) do not show any consistent pattern of hyporeactivity towards A alloantigens. These data include all spleen and PBL experiments which met the technical criteria of (1) the spontaneous medium release of ⁵¹Cr by target cells being less than 40% of maximum release and (2) at least 60% of the responders showing cytotoxic activity which titrated and which, on regression analysis, had an r^2 value of 0.80–1.00. The number of mice tested and assays performed that met these criteria are shown in Fig. 3, which also provides the pooled anti-A results of (1) all experiments performed using PBLs, (2) the data selected from the PBL experiments according to the criteria above and (3) spleen data, all of which met the criteria with the exception of one experiment. It is clear from Fig. 3a–c that there is no essential difference between the response of progeny of tolerant and of control fathers.

However, the pooling of data from many different experiments, each using a different batch of target cells, is not acceptable for statistical analysis, and weight was therefore placed only on the comparisons of animals tested within a single experiment. The data of 20 such experiments are shown as individual panels in Fig. 2. The results of each have been analysed by the Wilcoxon rank order test to determine whether the tolerant fathers or their progeny are significantly different from those of the normal fathers or their progeny. There is a highly significant difference between the response of the tolerant fathers and the control fathers (PBLs, panel 1a, $P < 0.001$; spleen, panel 1e, $P < 0.005$). There is also a difference in the response of experimental offspring in panel 3c (PBLs), with the male progeny of father 2A giving higher responses than the male progeny of control father 5C plus 8C. This difference is significant at the 0.05% level. However, panel 3g shows that the spleen responses of the same experimental mice were significantly lower ($P < 0.01$) than those of the controls 5C plus 8C, although the differences are quantitatively small. In the spleen experiment, moreover, the anti-B10 responses of the 2A progeny were lower than those of the controls 5C and 8C ($P < 0.02$). One further PBL experiment (Fig. 2, panel 3a) shows a significantly lower response ($P < 0.02$) by some of the progeny of father 10A than by some offspring of control father 4C (but not 2C), although this result was not reproducible (see panel 3b). These two positive results cannot therefore be held to carry any conviction—they seem to be non-reproducible and/or nonspecific. The results given in the remaining panels show no significant difference between the responses of experimental and control progeny. In each experiment the progeny of individual experimental fathers were compared with those of individual control fathers tested on the same occasion. All experiments completed but not shown in Fig. 2 because they failed to meet the technical criteria were nevertheless similarly analysed, again without detectable differences. Table 1 shows the numbers of offspring of each sex tested for each of the experimental and control fathers.

Our investigation extended the scope of the analysis described by Gorczynski and Steele¹ in that almost all offspring, including some that could not be included in the CML assay, eventually

Fig. 3 Anti-A cytotoxic responses of PBLs and spleen-pooled data. *a*, PBLs, unselected data. *b*, PBLs, selected data, $r^2 > 0.80$ in $> 60\%$ of mice in each experiment and spontaneous release $< 40\%$. *c*, Spleen data excluding one experiment. Cytotoxicity is at a K:T ratio of 5:1, derived from regression analysis.

received skin allografts bearing A strain antigens—a total of 193 experimental and 130 control mice. Of these, 80% had been tested for CML reactivity. In addition, the 10 experimental fathers were grafted with A strain skin, 4 of them (nos 1–4) at commencement and the remainder (nos 5–10) after completion of the breeding programme; all these fathers were fully tolerant and carried healthy grafts throughout their subsequent life (up to 11 months). Table 1 gives a detailed breakdown of the individual survival times of grafts transplanted to the experimental and control progeny and it identifies those mice that had been tested in CML and those (the minority) that had not. There is no discernible difference between experimental and control progeny. It is evident that strain A grafts were rejected swiftly and consistently by both male and female recipients, whereas F_1 grafts were rejected more variably, especially by males. The range of survival of grafts on experimental and control mice was closely similar and no graft showed long-term survival.

It is therefore clear that, using the same strain combination, we have been unable to confirm the CML results of Gorczynski and Steele, and the *in vitro* data receive full support from the skin graft assay. Reasons for the discrepancy between the CML data from the two studies can be looked for in the following points.

(1) The initial tolerance-conferring inoculum in our experiments consisted of 5×10^7 cells of a mixture of F_1 hybrid spleen and bone marrow cells, half the number reported by Gorczynski and Steele¹. Furthermore, the ratio of bone marrow cells to spleen cells was 1:10, compared with 1:1 in their study. However, a single dose of 5×10^7 lymphoid cells is certainly adequate for the induction and maintenance of skin graft tolerance and CML hyporesponsiveness (see above and Fig. 2, group B; also ref. 5); indeed, males receiving a single dose at birth had a CML reactivity indistinguishable from that of repeatedly injected males (group B versus group A of Fig. 2, panels 1a and 1e). We would therefore not expect these

differences in protocol to explain the discrepancy if tolerance is the criterion chosen. We have nevertheless begun further experiments in which mice have received 5×10^7 F₁ hybrid spleen and 5×10^7 bone marrow cells at birth, followed by subsequent doses of 5×10^7 spleen and bone marrow cells at a ratio of 1:1. Data from this additional study will not be available for some time.

(2) Although Gorczynski and Steele provide some documentation on the number of experimental fathers and their progeny, there is no information about their controls, which were presumably taken from standard stock without reference to known fathers. This point has been taken care of in our study.

(3) Although the sex of the experimental progeny is clearly shown in Gorczynski and Steele's pedigree diagram, there is no information about the sex of the controls in any one experiment (series), nor is it possible to ascertain what the sex of the stimulator and target cells was. It might therefore be argued that the responsiveness of males and females was different and that their representation in control and experimental groups was uneven, and/or that anti-H-Y responses biased their results. We investigated whether male and female responsiveness in the CML assay is indeed different. Two experiments using PBLs are shown in Fig. 2, panels 1d and 2d; there was no significant sex difference. It is true that another experiment using spleen cells (Fig. 2, panels 1g, 2g) did show a statistically significant difference ($P < 0.05$), with males giving a lower response than females, but quantitatively the difference is so small that it is unlikely to account for the discrepancy. Furthermore, as CBA females rarely make primary anti-H-Y responses⁶ their contribution in the Gorczynski and Steele study¹ can be expected to have been negligible.

(4) Gorczynski and Steele did not test either the injected fathers or their offspring with A/J skin allografts. In our study the experimental fathers were found to be fully non-reactive to skin allografts whereas all their offspring uniformly rejected their grafts.

(5) The CML sensitization and effector assays used by us were not precisely the same as those used by Gorczynski and Steele. They tested only spleen cells and the levels of cytotoxicity they reported¹ were much lower than those obtained in our spleen assays, but it is difficult to make comparisons as their report does not make it clear whether precise cell counts and full titrations were performed on the effector cells generated in culture. It is, however, striking that the low level of cytotoxicity described by them is comparable to the low levels observed by us in some of the experiments in which PBLs were used as responders. The cytotoxicity of both control and experimental mice here tended to be more variable and, we therefore reason, more likely to be sensitive to weak suppressor influences. Our PBL results are nevertheless quite indistinguishable from our spleen results, for neither differentiate between experimental and control offspring.

(6) Whereas all mice in our study were derived from strains bred at St Mary's Hospital Medical School, where the homozygosity of inbred strains is checked from time to time by syngeneic skin transplantation, the mice used by Gorczynski and Steele, although derived from the same foundation stock, were obtained from different breeding colonies. It is conceivable that this introduced a measure of genetic variability that could account for small differences in responsiveness.

(7) We used essentially the same kind of statistical analysis as Gorczynski and Steele. This analysis could fail to reveal a small proportion of non- or hyporesponders in individual experiments, but visual examination of the data suggests that this has not been the case.

It is difficult to account for the discrepancy in the two sets of findings by examining differences in the protocols used. There are available data from several other investigations designed to test the hypothesis put forward by Gorczynski and Steele¹, who have recently extended their observations to another strain combination and claim to have shown the simultaneous and independent inheritance of tolerance to two distinct haplo-

types⁷. R. B. Ashman, C. E. Woodhams and R. V. Blanden (personal communication) tested by CML and skin grafting the progeny of male CBA mice made tolerant at birth by injection of (CBA $\times$ BALB/c)F₁ cells; they did not differ from control progeny although one graft survived on an experimental mouse for a surprisingly long time and this mouse gave a low CML response. McLaren *et al.* (see accompanying letter⁸) examined by CML the reactivity of homozygous progeny of male B6 $\leftrightarrow$ BALB/c tetraparental chimaeric mice bred with both B6 and BALB/c females. The B6 progeny were not hyporesponsive to BALB/c alloantigens, nor were the BALB/c progeny hyporesponsive to B6. J. Craig Gray (personal communication) has been assessing the skin graft survival times in offspring of tolerant male rats, using grafts from the cell donor strain, and here again no hyporesponsiveness has yet been uncovered.

Using a rather different approach, Hašek *et al.*⁹ have been studying CML reactivity of first generation backcross mice of F₁ hybrid H-2 heterozygous fathers. It could be argued that it should follow from the hypothesis under discussion^{1,2} that the natural tolerance of an F₁ father is passed on to his homozygous progeny with respect to their reactivity to the alloantigens of his other parental haplotype. This is evidently not so. Along similar lines, and following the much earlier report of Guttman *et al.*¹⁰, Brent and Rayfield (unpublished data) have been breeding CBA fathers tolerant of A with (CBA $\times$ A)F₁ females to examine the ability of the progeny to reject A skin grafts. In this case positive results would be indicated by an abnormal number of offspring bearing long-surviving A strain grafts compared with control offspring of normal CBA males bred with (CBA $\times$ A)F₁ females. Although the study is not yet complete there are, to date, no differences between the control and experimental groups. Moving away from tolerance to alloantigens, A. Müllbacher, W. Fierz and J. Sheena (personal communication) have bred from CBA mice made tolerant to Bebaru virus by neonatal and subsequent weekly injections of virus inactivated by X-ray irradiation. The offspring of some of the tolerant fathers gave low responses to Bebaru virus, but these were not found in every experiment.

These experiments may be regarded as a test case for the validity of Lamarckian inheritance, which relates to the inheritance of acquired adaptations, not to the inheritance of the passively acquired somatic changes. An immunological response is surely the paradigm of physiological adaptations—witness the complete confidence with which an immunologist assumes that a rabbit not yet born will be able to make antibodies against a chemical not yet synthesized. There are technical difficulties in devising critical experiments on the inheritance of antibody formation but these do not apply to specific suppression of immune responsiveness (tolerance): it was therefore enterprising of Gorczynski and Steele to use acquired tolerance as the adaptive response on which to base their examination of Lamarckism. Unfortunately, our own findings do not support theirs and confirm the original observations by Billingham *et al.*¹¹ in the identical strain combination. We still believe that all experiments executed hitherto to corroborate the Lamarckian interpretation¹² can be faulted.

We thank Miss S. Kalsi, Miss M. Gaffey and Mr R. Butler for their technical assistance and the MRC and Joint Standing Research Committee of St Mary's Hospital for their support.

Steele and Gorczynski¹ have recently suggested that inbred male mice rendered tolerant at birth to the alloantigens of an H-2 plus non-H-2 incompatible inbred strain can transmit this tolerance or hyporeactivity, as measured in a primary anti-H-2 cytotoxic T-cell test *in vitro*, to their progeny, born of normally reactive females syngeneic with the males. As a corollary, it might be expected that the progeny of tetraparental males which are tolerant because from earliest fetal development they are chimaeric with respect to all tissues, including haematopoietic cells and germ cells, might in turn be tolerant to the other set of paternal alloantigens. We have now found, on the contrary, that inbred progeny of one component of a tetraparental male showed heightened responsiveness to the other paternal alloantigens.

We examined homozygous progeny of two C57BL/6 ↔ BALB/c male tetraparental chimaeras² with respect to their ability to mount primary anti-H-2 cytotoxic T-cell responses *in vitro* to either C57BL/6 (B6) (H-2^b) or BALB/c (H-2^d) and to a 'third party' strain, CBA (H-2^k). The two chimaeras were mated first with BALB/c females and of the resulting heterozygous (BALB/c × B6)_{F1} (agouti) and homozygous BALB/c (white) progeny, the homozygotes were kept and tested. The same tetraparental chimaeras were also bred with B6 females, the agouti (heterozygous B6 × BALB/c) progeny disposed of and the black (homozygous B6) kept and tested. The BALB/c and B6 mothers were mostly used for one litter only. We examined the cytotoxic T-cell responses of a total of 46 offspring from 13 litters, 7 with BALB/c and 6 with B6 mothers. The size of the litters of BALB/c mothers was not statistically different from those of the B6 mothers. There were 26 BALB/c progeny (13 males and 13 females) all of chimaera 1 and 20 B6 progeny (10 males and 10 females) of which 12 were fathered by chimaera 1 and 8 by chimaera 2. Both fathers were coat colour chimaeras but there is evidence only for number 1 being a germ-cell chimaera (see above). Chimaera 2 died before he could be tested for T-cell cytotoxic responses, but chimaera 1 was tested and found to be tolerant to each of the parental strains B6 and

Fig. 1 Anti-C57BL/6 responses of BALB/c progeny of B6 ↔ BALB/c chimaeras and control BALB/c fathers. Conditions of culture. PBLs: two to six 0.2-ml round-bottomed wells were set up with 1×10^5 responders plus 1×10^5 2,000 R irradiated spleen cells per well as antigen, in RPMI with 5% fetal calf serum, 5×10^{-5} M 2-mercaptoethanol, penicillin/streptomycin + glutamine. Spleen: 2×4 ml Linbro wells were set up with 1×10^7 responders + 1×10^7 2,000 R irradiated antigen per well in RPMI medium as above. Assay⁴ was on day 5 of culture. Cells were collected from wells, counted, plated and serially double diluted in round-bottomed 0.2-ml microtitre wells, to which were added a constant number of ⁵¹Cr-labelled target cells (24 h concanavalin A blast cells or thioglycollate-induced peritoneal macrophages) to give attacker:target (A:T) ratios starting at ~10:1. They were collected after 3 h incubation. Experimentally determined % specific lysis was subjected to regression analysis. The height of the bars shown is the % specific lysis at A:T 5:1 taken from this curve ($r^2 > 0.9$). The bars representing individual animals are placed in a ranked order.

BALB/c, but reactive to a third party strain, CBA (H-2^k) (Table 1). Previous investigations of chimaeras made in this laboratory have shown that the inability of such mice to make anti-parental cytotoxic responses does not depend on the level of haematopoietic chimaerism. All chimaeras tested were essentially tolerant³.

We used age-matched BALB/c and B6 litters as controls, born of individually identified fathers (four B6 and six BALB/c) and reared in the same environmental conditions as the chimaera progeny. In each experiment either all males or all females were used as responder, antigen and target. Each control and experimental mouse was tested on four different occasions each 2 weeks apart. On two occasions peripheral blood lymphocytes (PBLs) were prepared from blood samples taken by tail bleeding and set up in micromixed lymphocyte culture (MLC)⁴; on the third occasion a sample of spleen was removed for MLC from each mouse under general anaesthesia; finally, the mouse was killed and the remainder of the spleen taken for MLC. During the experiments, a few mice died and the number in each experiment was further reduced by occasional contamination of a culture.

Table 1 Tolerance to parental antigens of a tetraparental chimaera B6 ↔ BALB/c

Responder	Lysis on target		
	B6	CBA	BALB/c
BALB/c (6)	42	44	ND
B6 ↔ BALB/c	4	40	2
B6 (4)	ND	29	21

Tolerance is expressed as % specific lysis at A:T (attacker:target cell ratio) 5:1 in a cytotoxic T-cell response (method as in Fig. 1). Mean values for BALB/c + B6. ND, not done. Numbers of mice tested are given in parentheses.

Table 2 Mean cytotoxic responses of homozygous progeny of two C57BL/6 $\leftrightarrow$ BALB/c made tetraparental chimaeras

		PBLs		Spleen	
		1	2	1	2
B6 anti-BALB/c	E	40.9 (9)	44.2 (9)	26.4 (7)	11.1 (7)
	C	39.8 (10)	42.9 (10)	29.5 (10)	9.3 (10)
B6 anti-BALB/c	E	13.9* (8)	19.8 (8)	31.7 (8)	10.0 (5)
	C	9.1 (10)	18.8 (10)	31.6 (10)	14.4 (10)
BALB/c anti-B6	E	46.3 (10)	41.5† (11)	50.7 (12)	12.4 (10)
	C	39.9 (4)	20.4 (4)	48.9 (5)	9.2 (4)
BALB/c anti-B6	E	45.8 (11)	24.3 (10)	42.5§ (9)	9.8 (10)
	C	41.5‡ (11)	19.1 (11)	39.8 (10)	9.8 (12)

Mean cytotoxic responses are expressed as % specific lysis at A:T 5:1 in a cytotoxic T-cell response (method as in Fig. 1). E, experimental animals; progeny of B6 $\leftrightarrow$ BALB/c male chimaeras; C, control animals; age-matched normal animals. Numbers in parentheses are the number of animals tested.

* $P < 0.05$; † $P < 0.01$; ‡ $P < 0.01$; § $P < 0.05$ (Wilcoxon rank order test).

The mean anti-BALB/c and anti-B6 cytotoxic responses of the various groups are shown in Table 2. Statistical tests (Wilcoxon rank order test) were done on all experiments. The levels of cytotoxicity generated by B6 chimaera male progeny against BALB/c or third party CBA antigen did not differ significantly from those of age- and sex-matched controls. Among the B6 females cells from the chimaera progeny in one test showed significantly greater ($P < 0.05$) cytotoxicity against BALB/c antigen than did the controls, but this result was not confirmed on the three subsequent occasions, and as the ranking data were statistically heterogeneous, they could not be combined. When the responses of the progeny of chimaeras 1 and 2 were analysed independently the same results were obtained. In contrast, when the response of the BALB/c chimaera progeny to B6 antigen was compared with their BALB/c age- and sex-matched controls, a consistent increase in the level of cytotoxicity of the experimental versus control animals was found. Figure 1 shows the responses of all BALB/c progeny tested: for each sex the rank order results from the four occasions proved to be statistically homogeneous, that is, were consistent, and hence could be combined by ranking the summed rank orders. The excess of experimental over control cytotoxicity levels was, though small, statistically significant ($P < 0.01$) for both the male and female progeny independently. The responses of the BALB/c chimaera progeny to the third party control CBA were no different from that of control animals.

These results are in keeping with the findings of Brent *et al.* (see accompanying letter⁵), in that the state of tolerance manifest in male mice is not transmitted to their progeny. In fact, the difference that we observed was in the opposite direction to that predicted from the work of Gorczynski and Steele¹. It occurred whether or not the BALB/c young had F₁ littermates at birth, so is unlikely to be due to sensitization by antigens of litter mates during pregnancy. We are exploring the possibility that it may be mediated via the mother, perhaps as a result of sensitization by antigens present in the ejaculate.

Selective antagonists of benzodiazepines

W. Hunkeler, H. Möhler, L. Pieri, P. Polc, E. P. Bonetti, R. Cumin, R. Schaffner & W. Haefely*

Pharmaceutical Research Department, F. Hoffmann-La Roche & Co. Ltd, CH-4002 Basel, Switzerland

Benzodiazepines produce most, if not all, of their numerous effects on the central nervous system (CNS) primarily by increasing the function of those chemical synapses that use γ -amino butyric acid (GABA) as transmitter^{1,2}. This specific enhancing effect on GABAergic synaptic inhibition is initiated by the interaction of benzodiazepines with membrane proteins of certain central neurones, to which drugs of this chemical class bind with high affinity and specificity^{3,4}. The molecular processes triggered by the interaction of these drugs with central benzodiazepine receptors, and which result in facilitation of GABAergic transmission, are still incompletely understood. Theoretically, benzodiazepines could mimic the effect of hypothetical endogenous ligands for the benzodiazepine receptors, although there is no convincing evidence for their existence⁵; *in vitro* studies indicate that benzodiazepines might compete with a modulatory peptide which is present in the supramolecular assembly formed by GABA receptor, chloride ionophore and benzodiazepine receptor and which reduces the affinity of the GABA receptor for its physiological ligand⁶. The mechanisms of action of benzodiazepines at the molecular level are likely to be better understood following our recent discovery of benzodiazepine derivatives, whose unique pharmacological activity is to prevent or abolish in a highly selective manner at the receptor level all the characteristic centrally mediated effects of active benzodiazepines. Here, we describe the main properties of a representative of this novel class of specific benzodiazepine antagonists.

Working on a series of imidazodiazepines, we found compounds which were potent inhibitors of the specific high-affinity binding of ³H-diazepam to brain synaptosomal fractions, but which failed to produce any of the behavioural and neurological effects typical of benzodiazepines. Detailed analysis revealed that these compounds selectively and potently inhibit the central effects of classic benzodiazepines by acting as their antagonists at benzodiazepine receptors. From a large series of compounds we have selected Ro 15-1788 (Fig. 1) for clinical trials.

Ro 15-1788 is even less toxic than most of the classic benzodiazepines; the following approximate acute LD₅₀ values were determined: 4,000 mg per kg intraperitoneally (i.p.) and 4,300 mg per kg orally (p.o.) in mice, 1,360 mg per kg i.p. and 6,000 mg per kg p.o. in rats. In mice, rats, cats, dogs and squirrel monkeys the compound up to subtoxic doses produces none of the characteristic effects of benzodiazepine drugs, such as sedative, anticonvulsant, muscle relaxant and anticonflict effects. Ro 15-1788 is not a convulsant by itself, it fails to sensitize animals to chemical convulsants such as leptazol and lacks overt central stimulant activity in all species studied (L.P. *et al.*, in preparation).

Specific binding of ³H-diazepam to crude synaptosomal fractions of rat cerebral cortex⁴ was inhibited competitively by Ro 15-1788 (Fig. 2) with an IC₅₀ value of 2 nmol l⁻¹. This is about one quarter the value for diazepam in the same experimental conditions. Ro 15-1788 also dose dependently inhibited the binding in the brain of ³H-flunitrazepam injected intravenously (i.v.) in mice (H.M. *et al.*, in preparation); tested 15 min after

* To whom correspondence should be addressed.

p.o. administration, Ro 15-1788 was about half as potent as diazepam (ED_{50} values 4.0 and 1.7 mg per kg, respectively).

Three test procedures were adapted routinely to screen for potential benzodiazepine antagonism: the anti-leptazol test⁷, the horizontal wire test⁸ in mice and the antagonism of flunitrazepam-induced pre-anaesthesia in squirrel monkeys. In the first test, a supramaximal i.p. dose of leptazol (120 mg per kg) produced tonic seizures in all animals. Diazepam 5 mg per kg i.p. (twice the calculated ED_{90}) fully protected mice from tonic seizures when given 1 h before leptazol. Ro 15-1788 was administered p.o. or parenterally at various doses and varying times after diazepam and the number of animals developing tonic seizures in response to leptazol were counted. When given p.o. 15 min before leptazol (and 45 min after diazepam), Ro 15-1788 antagonized the anticonvulsant effect of diazepam with an ED_{50} of 2.8 mg per kg, but did not reduce the anticonvulsant action of phenobarbitone in the same test procedure.

In the horizontal wire test⁸, central depressant drugs dose dependently impair the ability of mice hung on a wire by their forepaws to heave themselves on to the wire with their hindlegs. Diazepam (3 mg per kg i.p.) reduced the number of mice performing on the horizontal wire by 70–100%. Ro 15-1788 given before, simultaneously with or after diazepam dose dependently attenuated and blocked the depressant effect of diazepam and of other benzodiazepines; when given 15 min after 3 mg per kg diazepam i.p. and tested over 30 min, the ED_{50} value for Ro 15-1788 was 0.2 mg per kg p.o. Ro 15-1788 by itself did not affect the performance of mice and up to very high doses (300 mg per kg) was unable to antagonize the depressant effect of phenobarbitone, meprobamate, ethanol, L-cycloserine (a GABA transaminase inhibitor) and muscimol. However, it antagonized the performance-depressant effect of zopiclone⁹, a non-benzodiazepine with diazepam-like activity and moderate potency as an inhibitor of specific ³H-diazepam binding to brain synaptosomes. A pre-anaesthetic state (loss of righting reflex, ataxia, sleep-like posture) was induced in squirrel monkeys by 3 mg per kg flunitrazepam i.v. When Ro 15-1788 was administered by stomach tube in doses between 10 and 100 mg per kg at the peak of flunitrazepam action, the monkeys stood up spontaneously within minutes and returned to normal behaviour for 2–4 h.

Increase of food-rewarded behavioural responses that are depressed by a punishment contingency is considered to be the most relevant available indication from animal experiments for anxiolytic activity in man. In the procedure used in the present experiments, rats were trained to press a lever for food reward; during 'conflict sessions', in which each lever-press was both rewarded with a food pellet and punished with an electric foot shock, the number of lever presses was markedly reduced. Diazepam (5 mg per kg p.o.) consistently increased the number of punished responses. Ro 15-1788 at 10 mg per kg p.o. prevented the antipunishment effect of diazepam.

Electrophysiological studies revealed the following effects of Ro 15-1788 (P.P. *et al.*, in preparation). In non-anaesthetized acute spinal cats the compound did not itself affect segmental dorsal root potentials and reflexes, polysynaptic ventral root reflexes and the spontaneous discharge rate of γ -motoneurons (for methods see ref. 10). The very potent benzodiazepine, Ro 11-3128 (3-methylclonazepam), at 0.1 mg per kg i.v., markedly

Fig. 1 Structural formula of Ro 15-1788 (ethyl-8-fluoro-5,6-dihydro-5-methyl-6-oxo-4H-imidazo[1,5-a]benzodiazepine-3-carboxylate).

Fig. 2 Inhibition of specific binding of ³H-diazepam (0.5–10 nmol l⁻¹) in rat cerebral cortex homogenate by Ro 15-1788. ○, 0.5 nmol l⁻¹; ▲, 2 nmol l⁻¹; △, 5 nmol l⁻¹; ●, no Ro 15-1788.

augmented the dorsal root potential (index of GABA-mediated primary afferent depolarization) and depressed polysynaptic ventral root reflexes and γ -motoneurone activity. These effects were dose dependently reversed by i.v. injections of Ro 15-1788. In non-anaesthetized 'encéphale isolé' rats, i.v. injections of the short-acting imidazobenzodiazepine, midazolam⁷, produced a dose-dependent decrease in the spontaneous multi-unit activity in the substantia nigra pars compacta and in the nucleus raphé dorsalis; a 50% decrease was achieved between 326 and 750 μ g per kg. Ro 15-1788 at 3 mg per kg i.v. reversed the effect of the highest dose of midazolam on the firing rate of these supposed dopamine and serotonin neurones. In the same rats essentially the same antagonism between midazolam and Ro 15-1788 was found on hippocampal neurones.

Ro 15-1788 antagonized characteristic biochemical changes induced in the brain by benzodiazepines (H.M. *et al.*, in preparation). These drugs consistently attenuate the neuroleptic-induced increase of homovanillic acid (HVA) in the rat brain (an index of dopamine turnover) by enhancing a GABAergic inhibitory influence on dopamine neurones¹¹. Ro 15-1788 dose dependently reversed the reduction by diazepam of the chlorpromazine-induced increase of HVA. Benzodiazepines and sedative drugs of diverse chemical classes decrease the cyclic 3',5'-guanosine monophosphate (GMP) content of the cerebellum in rats^{12,13}. Ro 15-1788 by itself did not affect the cerebellar cyclic GMP level, but dose dependently prevented (when given before) and attenuated or abolished (when given afterwards) the cyclic GMP reduction induced by diazepam. The reduction of cerebellar cyclic GMP by barbiturates, ethanol, meprobamate, muscimol and neuroleptics was unaffected by Ro 15-1788.

The antagonistic activity of Ro 15-1788 is not only selective for active benzodiazepines as distinct from non-benzodiazepine depressants but is also selective for benzodiazepine effects mediated by the so-called central type of benzodiazepine receptor as distinct from effects produced through peripheral types of receptor or through nonspecific interactions with

biological systems. For example, the antischistosomal effect of Ro 11-3128 (refs 14, 15) was not inhibited by Ro 15-1788 *in vitro* and *in vivo* (H. R. Stohler, personal communication); the antischistosomal activity of some 7-nitro-substituted benzodiazepine derivatives is mediated by a low-affinity binding site in the epidermis of schistosomes with a different ligand specificity from that of the central type of benzodiazepine receptor¹⁶. Ro 15-1788 also failed to antagonize the depression by benzodiazepines in high concentrations (10^{-5} – 10^{-3} mol l⁻¹) of contractile responses of the guinea pig ileum to transmural electrical stimulation, an effect which is probably due to a nonspecific membrane stabilizing action.

These results characterize Ro 15-1788 as a representative of a novel class of drugs that act as specific antagonists of CNS effects of active benzodiazepines as well as of non-benzodiazepines with affinity for the central type of benzodiazepine receptors. The discovery of such antagonists is analogous to that of opiate antagonists and has considerable practical and scientific implications. They should be useful as antidotes for intoxications involving overdoses of benzodiazepines. As non-toxic agents, they should be useful for abolishing or reducing central effects of benzodiazepines given for surgical or diagnostic interventions whenever an immediate reversal of benzodiazepine effects is required. Previous attempts to counteract benzodiazepine effects by cholinesterase inhibitors^{17,18} or naloxone^{19,20} have yielded erratic results. Diagnostically, benzodiazepine antagonists should easily unmask the presence of active amounts of benzodiazepines in the CNS. Ro 15-1788 will be used to prevent the undesired central effects of Ro 11-3128 (3-methylclonazepam), which has proved effective as a one-shot treatment of schistosomiasis. Indeed, pilot studies in human volunteers have demonstrated a good tolerance and lack of intrinsic pharmacological effects of Ro 15-1788 as well as its ability to antagonize sedation induced by Ro 11-3128 (A. Darragh, personal communication). As research tools, Ro 15-1788 and other specific benzodiazepine antagonists will be extremely useful in defining the structural properties required for molecules to be recognized and bound by benzodiazepine receptors and to induce or prevent those conformational changes in the receptor protein that result in the typical enhancement of GABAergic transmission. Benzodiazepine antagonists should also be powerful tools in studying the possible existence of endogenous ligands for benzodiazepine receptors. Our screening for benzodiazepine antagonistic activity resulted in the identification of many compounds possessing either pure antagonistic or antagonistic properties combined with weak agonistic activity and revealed interesting and unexpected structure-activity relationships.

Purified EGF receptor-kinase interacts specifically with antibodies to Rous sarcoma virus transforming protein

Michael Chinkers & Stanley Cohen

Department of Biochemistry, Vanderbilt University School of Medicine, Nashville, Tennessee 37232, USA

Transformation by several RNA tumour viruses seems to be mediated by virally coded protein kinases which specifically phosphorylate tyrosine^{1–7}. A tyrosine-specific protein kinase also seems to be involved in the mitogenic action of epidermal growth factor (EGF)⁸. This EGF-stimulated kinase activity is closely associated with the EGF receptor, with which it copurifies during EGF-affinity chromatography⁹. Because both the virus- and EGF-stimulated tyrosine kinases may be involved in stimulation of cell growth, and because the viral kinases may be antigenically related to normal cell proteins^{5,10–12}, we examined the interaction of antibodies to viral tyrosine kinases with the affinity-purified EGF receptor-kinase preparation. We report here that the receptor-kinase specifically phosphorylates antibodies directed against the transforming protein kinase pp60^{src} of Rous sarcoma virus. However, none of these antibodies, including those which cross-react with the normal cellular homologue of pp60^{src} (pp60^{src}), precipitate the receptor-kinase. These results suggest that the EGF receptor-kinase is related to, but probably not identical with, pp60^{src}.

Antisera from rabbits bearing tumours induced by Rous sarcoma virus (TBR sera) not only precipitate pp60^{src} (ref. 13), but also have the unusual property of acting as a specific substrate for the protein kinase activity of pp60^{src}. In this reaction, pp60^{src} catalyses the phosphorylation of the IgG heavy chain^{14,15}, but does not phosphorylate normal rabbit IgG^{16,17}; TBR IgGs are not substrates for protein kinases in general¹¹. Using TBR sera obtained from several laboratories, we examined the ability of the EGF receptor-kinase to phosphorylate specifically the IgG heavy chain of TBR sera.

Affinity-purified EGF receptor-kinase, prepared from membranes of A431 cells⁹, was incubated with various antisera in the presence of EGF, Mn²⁺ and [γ -³²P]ATP and subjected to SDS-gel electrophoresis and autoradiography (Fig. 1). As previously reported, in the absence of added serum the receptor-kinase catalyses the phosphorylation of two bands with apparent molecular weights (MWs) of 150,000 and 170,000 (Fig. 1, lane a)—this doublet is thought to be the EGF receptor itself⁹. When TBR serum is included in the reaction mixture, a band comigrating with the IgG heavy chain becomes phosphorylated (Fig. 1, lanes b–f). This phosphorylation seems to be more pronounced when TBR sera that cross-react with the normal cellular homologue (pp60^{src}) of pp60^{src} are used (Fig. 1, lanes d–f). Normal rabbit sera are not phosphorylated or are phosphorylated only to a small extent (Fig. 1, lanes g, h). We tested 30 antisera to various proteins and viruses in this assay, and, with the exception of TBR sera, none was phosphorylated by the EGF receptor-kinase. These controls included antisera which precipitate the tyrosine kinases associated with Abelson murine leukaemia virus¹, feline sarcoma virus⁵ and polyoma virus¹⁸, as well as an antiserum to A431 cell membranes that precipitates the receptor-kinase (Fig. 1, lane i)¹⁹. Thus, the EGF receptor-kinase interacts specifically with antisera that precipitate pp60^{src}.

The observed phosphorylation of TBR IgG was not due to endogenous protein kinase activity in the TBR sera or to an EGF-unrelated cellular kinase in the purified receptor prep-

Fig. 1 Analysis by SDS-gel electrophoresis and autoradiography of EGF receptor-kinase-catalysed phosphorylation of rabbit anti-tumour sera. Antisera from rabbits bearing tumours induced by Rous sarcoma virus (TBR sera)¹³ were able to precipitate and act as a substrate for the transforming protein kinase coded for by Rous sarcoma virus (pp60^{src})^{14,15}. The antisera shown in lanes *d-f* can also precipitate, and be phosphorylated by, the homologous cellular pp60^{src} (ref. 11). Rabbit antiserum raised against A431 human epidermal carcinoma cell membranes was prepared and purified as described elsewhere¹⁹; this antiserum precipitates the purified EGF receptor with its associated tyrosine-specific⁸ protein kinase activity (EGF receptor-kinase). The EGF receptor-kinase was purified from Triton/glycerol-solubilized A431 cell membranes by adsorption to EGF-AffiGel and elution with ethanolamine as described elsewhere⁹. The receptor-kinase preparation used in these experiments contained ~90 µg ml⁻¹ of protein in 1% Triton X-100, 10% glycerol, 5 mM ethanolamine, pH 7. 15 µl of receptor-kinase was activated⁹ by incubation for 10 min at 25 °C with 15 µl EGF (100 ng, in 0.05% bovine serum albumin (BSA)) and 15 µl of 4 mM MnCl₂ in 60 mM HEPES, pH 7.4 (HEPES/Mn²⁺). The mixture was then chilled on ice for 10 min and incubated with 3 µl of the indicated antiserum for 30 min at 0 °C. 15 µl [γ -³²P]ATP (2 µCi, 60 µM) was then added, and after 10 min at 0 °C the phosphorylation reaction was terminated by addition of SDS sample buffer to the final concentrations described by Laemmli²¹. Samples were heated for 5 min in a boiling water bath and electrophoresed through a 3% polyacrylamide stacking gel and a 7.5% separating gel using Laemmli's buffer system²¹. ³²P-labelled proteins were visualized by autoradiography on DuPont Cronex film, while molecular weight markers (BioRad) and the IgG heavy chain were located by Coomassie blue staining. Markers were myosin, MW 200,000 (200 K); β -galactosidase, MW 117 K; phosphorylase *b*, MW 94 K; BSA, MW 68 K, and ovalbumin, MW 43 K. Serum additions were as follows: *a*, saline control; *b-f*, TBR sera; *g*, *h*, normal rabbit sera; *i*, rabbit anti-A431 cell membrane IgG (25 µg).

ation (Fig. 2) because no phosphorylation of IgG was observed in any of the TBR sera in the absence of added receptor-kinase (Fig. 2, lane *a*), and phosphorylation of the IgG heavy chain was stimulated by EGF (Fig. 2, lanes *b*, *c*).

Surprisingly, despite the specific interaction of the EGF receptor-kinase with TBR IgG, none of the TBR sera examined was able to precipitate the receptor-kinase, including antisera known to precipitate pp60^{src} from uninfected cells (Fig. 3). The receptor doublet and the IgG heavy chain were labelled with ³²P by incubating receptor-kinase with TBR serum in the presence of EGF, [γ -³²P]ATP and Mn²⁺ (Fig. 3, lane *a*). This prelabelled mixture was then subjected to immunoprecipitation with protein A-Sepharose, and the supernatant (Fig. 3, lane *b*) and washed pellet (Fig. 3, lane *c*) were examined by SDS-gel electrophoresis and autoradiography. The phosphorylated IgG is precipitated but the receptor remains in the supernatant. However, as it is possible that the receptor and kinase are dissociable, this experiment was not adequate to determine

whether the receptor-associated kinase activity had remained in the supernatant or had been precipitated with the TBR IgG. Therefore, unlabelled EGF receptor-kinase, pre-activated with EGF, was incubated with unlabelled TBR serum, immunoprecipitated with protein A-Sepharose, and the supernatant and washed pellet were assayed for protein kinase activity in the presence of [γ -³²P]ATP and Mn²⁺. All phosphorylating activity was found in the supernatant, where the receptor doublet became phosphorylated (Fig. 3, lane *d*), whereas the IgG-containing precipitate contained no detectable kinase activity (Fig. 3, lane *e*). Thus, neither the EGF receptor nor its associated protein kinase activity is precipitated by TBR serum. The antisera to other viral tyrosine kinases (see above) also failed to precipitate the EGF receptor (not shown). As a positive control, it was confirmed that this TBR serum could precipitate IgG kinase activity from a crude detergent extract of A431 cells (Fig. 3, lane *g*). Thus, although A431 cells seem to contain pp60^{src} that precipitates with and phosphorylates TBR serum, this kinase is not detected in the purified receptor preparation. Furthermore, in these conditions both the receptor and its associated kinase activity could be immunoprecipitated using antiserum directed against the A431 cell membranes from which the receptor-kinase was purified (Fig. 3, lane *f*). In this experiment, unlabelled receptor-kinase, precipitated with the anti-membrane serum, became labelled in the immunoprecipitate on addition of [γ -³²P]ATP and Mn²⁺; the antibody was not labelled.

Because phosphorylation of IgG catalysed by pp60^{src} and phosphorylation of the 150,000–170,000 MW EGF receptor doublet by the receptor-kinase are known to occur on tyrosine residues^{2,8}, it was interesting to determine whether the IgG phosphorylation catalysed by the receptor-kinase was also specific for tyrosine (Fig. 4). TBR IgG was phosphorylated in the presence of the receptor-kinase and [γ -³²P]ATP, and precipitated with protein A-Sepharose; the precipitated material was eluted from the washed beads by heating in SDS, and SDS-gel electrophoresis and autoradiography of an aliquot of this eluate were used to confirm that the only major phosphorylated component was the IgG heavy chain (Fig. 4*a*). The remainder of the eluted material was subjected to partial acid hydrolysis and paper electrophoresis at pH 3.5 in the presence of internal phosphoamino acid standards⁸. With or without EGF,

Fig. 2 Effect of EGF on receptor-kinase-catalysed phosphorylation of TBR serum. Phosphorylation reactions, electrophoresis and autoradiography were carried out as described in the legend to Fig. 1, except that buffer blanks were substituted for EGF or for EGF receptor-kinase as indicated. *a*, Minus receptor-kinase, +EGF, +TBR serum; *b*, plus receptor-kinase, -EGF, +TBR serum; *c*, plus receptor-kinase, +EGF, +TBR serum. Similar results (not shown) were obtained with the other TBR sera described in Fig. 1 legend.

Fig. 3 SDS-gel electrophoresis and autoradiography showing non-precipitation of EGF receptor-kinase by TBR serum. *a-c*, Mixtures of EGF receptor-kinase and TBR serum (known to cross-react with pp60^{src}) were phosphorylated as described in Fig. 1 legend, except that the final reaction volume was increased to 83 μ l. *a*, This phosphorylated mixture was subjected to SDS-gel electrophoresis without further treatment; *b, c*, IgG in a replicate phosphorylated mixture was adsorbed to 40 μ l of packed protein A-Sepharose in 20 mM HEPES, pH 7.4 by incubation for 30 min at 0°C with resuspension every 5 min. The sample was then spun for 2 min at 8,000g in an Eppendorf minifuge, and 60 μ l of the supernatant prepared for electrophoresis (lane *b*). The protein A-Sepharose beads were washed five times with 1 ml of 20 mM HEPES, pH 7.4. The bound IgG was eluted by heating for 5 min at 100°C in 150 μ l of SDS sample buffer, and, after removal of the protein A-Sepharose beads by centrifugation, was subjected to SDS-gel electrophoresis (lane *c*). *d, e*, Unlabelled receptor-kinase was activated with EGF and incubated with TBR serum as in *a-c*. Following incubation, IgG was precipitated with protein A-Sepharose as described above for lanes *b* and *c*; 60 μ l of the supernatant was incubated for 10 min at 0°C with 20 μ l each HEPES/Mn²⁺ and [γ -³²P]ATP (2.0 μ Ci, 60 μ M) and processed for electrophoresis (lane *d*). The protein A-Sepharose precipitate was washed five times with 1 ml of 20 mM HEPES, pH 7.4, and incubated for 10 min at 0°C with 20 μ l each HEPES/Mn²⁺ and [γ -³²P]ATP. IgG bound to the protein A-Sepharose was eluted as for *c* and electrophoresed (lane *e*). *f, g*, Positive controls for immunoprecipitation: *f*, as lane *e*, except that rabbit IgG raised against A431 cell membranes was used in place of TBR serum; *g*, a crude 1% Triton/10% glycerol extract of unlabelled A431 cells was incubated with cross-reactive TBR serum and immunoprecipitated. Precipitation with protein A-Sepharose and phosphorylation of the precipitate with [γ -³²P]ATP was as for samples *e* and *f*.

the major phosphoamino acid released by hydrolysis of the phosphorylated IgG was identified as phosphotyrosine; the amount of phosphotyrosine formed was greater in the presence of the hormone. Thus, phosphorylation of TBR IgG by either pp60^{src} (ref. 2) or by the EGF receptor-kinase occurs on tyrosine.

The previous findings that both pp60^{src} (refs 2, 4) and the EGF receptor-kinase⁸ phosphorylate only tyrosine residues suggested some possible similarity in the active sites of the two enzymes. Our observation that both kinases specifically phosphorylate TBR IgG, although other IgGs contain tyrosine residues, suggests further similarity. However, there are several interpretations of the degree of this similarity: (1) TBR IgG, although not substrates for cyclic AMP-dependent protein kinases¹¹, may contain sequences that make them efficient substrates for a variety of related tyrosine-specific protein kinases. In this regard, it is interesting that the tyrosine kinase activities associated with the transforming proteins of feline sarcoma virus, Abelson murine leukaemia virus, polyoma virus, and the avian sarcoma viruses Y73 and PRC II are able specifically to phosphorylate TBR IgG (K. Beemon and T. Hunter, personal communication). (2) The EGF receptor-kinase may be

sufficiently antigenically related to pp60^{src} specifically to bind and phosphorylate anti-pp60^{src} IgG, but insufficiently related to bind tightly enough for immunoprecipitation. (3) The receptor-kinase may be pp60^{src}, but the interaction of pp60^{src} with the EGF receptor may inhibit the ability of the kinase to be immunoprecipitated by TBR IgG.

Although further purification of the receptor-kinase will be required to distinguish unambiguously between the above possibilities, we find it intriguing that an EGF-stimulated enzyme which seems to be involved in normal growth control interacts specifically with antibodies to a viral transforming protein. It is possible that the normal cell proteins from which viral transforming proteins are thought to have evolved²⁰ may, like the EGF receptor-kinase, be part of the normal cell machinery involved in growth regulation. Furthermore, as EGF is not tumorigenic, we believe that study of the means by which different tyrosine kinases stimulate growth may elucidate the cellular controls that distinguish malignant from non-malignant growth.

Fig. 4 Identification of phosphotyrosine in TBR IgG phosphorylated by the EGF receptor-kinase in the absence/presence of EGF. 40 μ l of the receptor-kinase preparation was mixed with 40 μ l of HEPES/Mn²⁺ and 40 μ l of either 0.05% BSA without EGF, or 0.05% BSA containing 270 ng EGF, and was incubated for 10 min at 25°C. The mixture was chilled on ice for 10 min and incubated for 1.5 h at 0°C with 6 μ l of TBR serum. 4.5 μ l of [γ -³²P]ATP (35 μ Ci, 436 μ M) was then added, and incubation on ice was continued for 10 min. 40 μ l of protein A-Sepharose in 20 mM HEPES, pH 7.4 was then added, and the suspension incubated for 30 min on ice, with resuspension every 5 min. The protein A-Sepharose was washed five times with 1 ml of 20 mM HEPES, pH 7.4 by spinning for 2 min at 8,000g in an Eppendorf minifuge, and the bound IgG was eluted by adding 600 μ l of 2% SDS in 20 mM HEPES, pH 7.4 and heating for 5 min in a boiling water bath. Aliquots (50 μ l) of each sample were examined by SDS-gel electrophoresis and autoradiography (*a*). The remainders of the samples were transferred to glass centrifuge tubes on ice and precipitated with 20% trichloroacetic acid (TCA) in the presence of 100 μ g BSA and 10 mM sodium pyrophosphate. Precipitates were washed twice with 20% TCA/10 mM sodium pyrophosphate and once each with ethanol and ether. Samples were air dried, hydrolysed under vacuum in 6 M HCl for 2.5 h at 100°C, and processed for paper electrophoresis at pH 3.5, as described elsewhere⁸. Results of paper electrophoresis and autoradiography are shown in *b*. Internal phosphoamino acid standards⁸ were located by staining with ninhydrin.

We thank Drs J. M. Bishop, D. Baltimore, T. Hunter, M. Barbacid and R. Erikson for their gifts of antisera, and Martha Reich and Katherine Chen for technical assistance. This work was supported by USPHS grant HD-00700. S.C. is an American Cancer Society Research Professor.

Anti-pp60^{src} antibodies are substrates for EGF-stimulated protein kinase

Jeffrey E. Kudlow, Janice E. Buss & Gordon N. Gill

Department of Medicine, Division of Endocrinology, University of California, San Diego, School of Medicine, La Jolla, California 92093, USA

Epidermal growth factor (EGF) stimulates phosphorylation of its own receptor at a tyrosine residue¹. Similarly, the viral gene product pp60^{src}, which is responsible for cellular transformation by avian sarcoma virus (ASV), phosphorylates itself and immunoglobulin directed against pp60^{src} at tyrosine residues^{2,3}. This unusual site of phosphorylation catalysed by two membrane-associated protein kinases⁴⁻⁷ involved in growth control prompted us to study the immunological relatedness of the EGF-stimulated protein kinase and the pp60^{src}. Using anti-pp60^{src} antisera, we attempted to immunoprecipitate the EGF-stimulated protein kinase solubilized from plasma membranes. We report here that neither the EGF-stimulated kinase nor the EGF receptor were immunoprecipitable by anti-pp60^{src} sera. However, anti-pp60^{src} IgG served as a specific substrate for the EGF-stimulated kinase, suggesting a close similarity between the EGF-stimulated kinase and pp60^{src}.

We used the plasma membranes of A431 human carcinoma cells because of their unusually high density of EGF receptors⁸. Detergent-solubilized plasma membranes prepared from these cells retain EGF-stimulated phosphorylation of the EGF receptor protein⁹ of molecular weight (MW) ~170,000. Treatment of the solubilized membranes with antisera raised in ASV tumour-bearing rabbits¹⁰ was followed by removal of the immune complexes with protein A containing *Staphylococcus aureus* (Pansorbin, Calbiochem). Phosphorylation of immune, but not control, IgG heavy chains could be demonstrated in the resultant precipitate. Normal or non-ASV-transformed vertebrate cells contain *src* gene sequences and a cell protein

(pp60^{src}) that is closely related to the viral pp60^{src} (refs 11-14). Our ability to precipitate specifically a rabbit IgG heavy chain kinase with anti-pp60^{src} sera suggested that the A431 plasma membrane contained pp60^{src}.

Using this immunoprecipitation approach, we determined the effect of removal of pp60^{src} activity on EGF-stimulated phosphorylation of the EGF receptor. The membranes were solubilized using a procedure that optimized the recovery of pp60^{src} activity in the immunoprecipitates and the solubilized A431 membranes were then titrated with antiserum to determine the amount required to remove the maximum quantity of pp60^{src} activity made available by membrane solubilization. As determined by this titration, doubling of the amount of antiserum did not increase the amount of pp60^{src} activity precipitated. However, another incubation with additional antiserum in the immune adsorbed supernatant detected some residual pp60^{src} activity (Fig. 1, lane 8), which never exceeded 25% of the total immunoprecipitable activity. A third immune precipitation failed to detect any residual pp60^{src} activity. When immunoprecipitates were formed from solubilized plasma membranes

Fig. 1 Effect of immunoprecipitation of pp60^{src} activity on EGF-stimulated phosphorylation of the EGF receptor in solubilized A431 cell membranes. Purified A431 plasma membranes¹⁷ were solubilized in buffer containing 1% Triton X-100, 10% glycerol, and 20 mM HEPES, pH 7.4 (ref. 9). Control (lanes 1, 2) and anti-pp60^{src} (lanes 3, 4) sera at a final dilution of 1/20 were incubated with 400 µg ml⁻¹ of solubilized A431 membrane for 3 h in 20 mM HEPES, pH 7.4, 1 mM MnCl₂, and 0.1 mg ml⁻¹ bovine serum albumin (BSA). Control (lane 5) and immune (lane 6) IgG were removed from the mixture by precipitation with Pansorbin for quantitation of pp60^{src} activity and the remaining supernatants divided into two aliquots: one was treated with (lanes 2, 4) or without (lanes 1, 3) 0.3 µM EGF (ref. 9) followed by the addition of 15 µM [γ -³²P]ATP (1.25 µCi per 60 µl assay). After incubation for 2 min at 0°C, the reaction was stopped by the addition of Laemmli sample buffer¹⁸ and boiling for 3 min, followed by electrophoresis on 7.5% polyacrylamide gels. Phosphorylated proteins were visualized by autoradiography. To quantify residual pp60^{src} present in control and immune supernatants, second aliquots of supernatant were again treated with anti-pp60^{src} serum and Pansorbin. These second immune precipitates derived from control (lane 7) or immune (lane 8) serum-treated supernatants were assayed for pp60^{src} activity. The Pansorbin-bound immune precipitates were washed three times by centrifugation in NP40 buffer¹⁹, once in phosphate-buffered saline, and resuspended in 80 µl of a buffer containing 20 mM sodium phosphate (pH 7.2), 5 mM MgCl₂ and 15 nM [γ -³²P]ATP (3,000 Ci mmol⁻¹, 2 µCi per assay). After incubation for 20 min at 30°C, the reaction was stopped by the addition of RIPA buffer²⁰, and phosphorylated proteins were separated on 10% polyacrylamide gels. The peptides present in the immunoprecipitates were analysed (lanes 9, 10). A431 cells were metabolically labelled with ³⁵S-methionine¹⁴, the plasma membranes isolated and solubilized and immunoprecipitations performed. The Pansorbin-bound immunoprecipitates from solubilized membranes that had been pre-adsorbed with control (lane 9) or immune (lane 10) serum were washed extensively before separation on 10% polyacrylamide gels. Molecular weight standards were: myosin, MW 200,000 (200 K); β -galactosidase, 130 K; phosphorylase b, 94 K; transferrin, 75 K; BSA, 68 K; catalase, 60 K; ovalbumin 43 K, and carbonic anhydrase, 30 K. C designates treatment with control serum, I with anti-pp60^{src} serum and C+I or I+I, sequential treatment with these sera.

Table 1 EGF-stimulated phosphorylation of tyrosine residues in the EGF receptor and in anti-pp60^{src} IgG

	³² P incorporation into tyrosine residues (c.p.m.) EGF receptor (MW ~ 170,000)	IgG heavy chain (MW = 55,000)
-EGF	156	147
+EGF	349	513

Phosphorylation reaction mixtures containing solubilized A431 membranes and anti-pp60^{src} serum with or without 0.3 μ M EGF were incubated as described in the legends to Figs 1 and 2. After electrophoresis, the gels were dried and the phosphorylated EGF receptor and IgG heavy chain located by autoradiography using appropriate alignment markers. The regions of the dried gel containing the phosphoproteins were cut out and placed in dialysis bags after removal of the paper backing. Buffer containing freshly prepared 10 mM NH_4HCO_3 , 0.1% SDS and 5% 2-mercaptoethanol was placed in the dialysis bag to swell the gel. The dialysis bags were placed in the same buffer between two platinum electrodes and a 5–10 V cm^{-1} field applied for 8 h; the field was reversed for 15 s before removal of the contents. This solution was filtered through glass wool and 50 μ g of bovine γ -globulin carrier added before trichloroacetic acid (TCA) precipitation. The protein precipitate was washed in ethanol and ether and hydrolysed for 2 h in 6 M HCl at 110 °C. Phosphoamino acids were separated by electrophoresis on cellulose thin layer plates with the buffer (pH 3.5) described by Hunter and Sefton⁷. ³²P-labelled amino acids were located by autoradiography and identified by alignment with the corresponding ninhydrin-stained phosphoamino acid standards. The area of the thin layer plate corresponding to phosphotyrosine was scraped and its ³²P content determined by scintillation counting.

prepared from ³⁵S-methionine-labelled A431 cells, several peptides were precipitated nonspecifically (data not shown). However, if immunoprecipitates were formed from solubilized membranes pre-adsorbed with control serum, a peptide of MW 60,000 was evident. Pre-adsorption with anti-pp60^{src} serum markedly and specifically diminished the amount of the 60,000-MW peptide in the immunoprecipitate, approximately in proportion to the removal of anti-pp60^{src} IgG kinase activity (Fig. 1, lanes 9, 10). Despite specific removal of >75% of the pp60^{src} activity and the associated 60,000-MW peptide from the solubilized membrane, EGF-stimulated phosphorylation of the ~170,000-MW receptor protein was unaffected (Fig. 1, lanes 1–4). Furthermore, analysis of the products of phosphorylation of the immunoprecipitate never revealed the ~170,000-MW receptor (Fig. 1, lanes 6–8) nor could EGF receptor phosphorylated before immunoprecipitation be detected in the immunoprecipitates (See Fig. 3b). Thus, neither the EGF receptor nor the EGF-stimulated protein kinase was removed by immunoprecipitation. These data suggested that either the pp60^{src} was immunologically unrelated to the EGF-stimulated kinase or that it was unavailable for immune adsorption.

In view of these experiments, we were surprised with the results obtained when solubilized A431 membranes were incubated with antisera which were not subsequently removed with Pansorbin: in these conditions, both the receptor and the heavy chains of anti-pp60^{src} IgG, but not control IgG, were phosphorylated in an EGF-stimulated manner (Fig. 2, upper panel). Antisera raised in several ASV tumour-bearing rabbits were phosphorylated by the solubilized membranes to varying extents. Those antisera which were good substrates for the solubilized EGF-stimulated kinase were also good substrates in the immunoprecipitation reaction designed to detect pp60^{src} activity (Fig. 2, lower panel). Because these antisera were selected for their ability to be phosphorylated by pp60^{src}, they did not always have parallel ability to act as substrate for pp60^{src}. Various non-immune sera failed to serve as phosphorylation substrates for either kinase. The parallel ability of the immune antisera to act as substrates for pp60^{src} and the EGF-stimulated kinase suggested that very similar determinants are required by the pp60^{src} and the EGF-stimulated kinase to allow phosphorylation of the anti-pp60^{src} sera.

The phosphoamino acids in the receptor and IgG heavy chain were analysed in phosphoproteins purified by polyacrylamide gel electrophoresis. Both the receptor and IgG were phosphorylated exclusively at tyrosine residues, and phosphate

incorporation into tyrosine in both proteins was stimulated threefold by EGF (Table 1).

The EGF stimulation of IgG phosphorylation was not due to the release of more pp60^{src} into an immunoreactive fraction because EGF failed to increase significantly the yield of pp60^{src} activity in the immune precipitate (data not shown). Furthermore, removal of a significant fraction of pp60^{src} did not alter the ability of the EGF-stimulated kinase to phosphorylate immune IgG (Fig. 3a). The inability to alter the receptor or immune IgG phosphorylation by prior immunoprecipitation of pp60^{src} suggested that these proteins were not phosphorylated by the fraction of pp60^{src} accessible to immunoprecipitation. The failure to immunoprecipitate the EGF receptor or its EGF-stimulated kinase, which is tightly associated with the EGF receptor, was not due to any impediment to binding of the Fc fragment of IgG to the protein A on the bacteria. Pansorbin could quantitatively remove antibodies which had been interacted with the EGF-stimulated kinase and phosphorylated. However, such immune precipitation did not precipitate the phosphorylated EGF receptor (Fig. 3b).

The apparent low affinity of the anti-pp60^{src} IgG for the EGF-stimulated kinase, which allowed phosphorylation but not immune precipitation, has two possible explanations. (1) The EGF-stimulated kinase could be distinct from the pp60^{src} yet similar enough to allow immune-specific recognition of antisera leading to IgG heavy chain phosphorylation. A closer homology between pp60^{src} kinase and EGF-stimulated kinase cannot be excluded. The tight association between the kinase and receptor could occlude some immune determinants, allowing the anti-pp60^{src} IgG to interact strongly enough for phosphorylation, but too weakly for immune precipitation. (2) It is possible that the phosphorylation site in the variable region of the heavy chain¹⁵ of anti-pp60^{src} contains a sequence that is preferred by tyrosine-specific kinases.

In either case, a close similarity between pp60^{src} and the EGF receptor kinase has been established. Both proteins are themselves phosphorylated at tyrosine residues and both are able to

Fig. 2 EGF-stimulated phosphorylation of anti-pp60^{src} sera. Various antisera to viral pp60^{src} were raised in newborn rabbits bearing ASV-induced tumours¹⁰. Sera from newborn rabbits that did not develop tumours contained no detectable anti-pp60^{src} activity—these and several adult rabbit sera served as controls. Control sera (lanes 1, 2) and immune sera (lanes 3–10) were incubated with solubilized A431 membranes for 30 min at 0 °C as described in Fig. 1 legend, without the addition of Pansorbin. Reaction mixtures were treated with (lanes 2, 4, 6, 8, 10), or without (lanes 1, 3, 5, 7, 9), 0.3 μ M EGF followed by the addition of 15 μ M [γ -³²P]ATP for 2 min at 0 °C. Electrophoresis and autoradiography were performed as described in Fig. 1 legend. Numbers below the autoradiogram show results for the same antisera when tested for ability to precipitate, and be phosphorylated by, cellular pp60^{src} from solubilized A431 membranes and by partially purified pp60^{src} (ref. 15) from ASV-induced chicken tumours. Immunoprecipitations and phosphorylation reactions were carried out as in Fig. 1 legend except that the reactions were terminated by applying the reaction mixtures to Whatman 3M filter paper discs which were then placed in 10% TCA. The filters were washed three times in 5% TCA, then boiled in 5% TCA for 10 min; TCA and water were then removed by washing the filters in ethanol, followed by ether. ³²P incorporated into IgG heavy chains was measured by scintillation counting.

Fig. 3 *a*, Lack of effect of removal of pp60^{src} on EGF-stimulated phosphorylation of anti-pp60^{src} serum. pp60^{src} was removed from solubilized A431 membranes by immunoprecipitation with anti-pp60^{src} serum. The same quantity of antiserum was re-added to control (lanes 1, 2) and immune (lanes 3, 4) serum-treated supernatants. Mixtures were incubated for 30 min at 0°C followed by addition of EGF (lanes 2, 4) or buffer (lanes 1, 3). Phosphorylation reactions, electrophoresis and autoradiography were performed as described in Fig. 1 legend. *b*, Failure of anti-pp60^{src} serum to precipitate the phosphorylated EGF receptor. Immune serum and EGF were added to solubilized A431 cell membranes as described in Fig. 2 legend. [γ -³²P]ATP (15 μ M) was added for 5 min at 0°C and the reaction terminated by addition of EDTA to a final concentration of 5 mM. Immunoprecipitation was carried out using Pansorbin. Samples were analysed by electrophoresis and autoradiography. Lane 5, supernatant remaining after immunoprecipitation; lane 6, complete phosphorylation mixture; lane 7, immunoprecipitate.

phosphorylate, with parallel avidity, antisera directed against pp60^{src}, also at tyrosine residues. Although identity of the EGF-stimulated kinase with the pp60^{src} has not been established, these two kinases belong to a new family of tyrosine kinases involved in the continuum from growth control to transformation. It has been suggested that ASV transformation is an exaggerated growth response resulting from a 30- to 50-fold increase in the amount of pp60^{src} in the transformed cells¹². Although EGF stimulation does not result in transformation, sarcoma growth factor, described by DeLarco and Todaro¹⁶, does induce a transformation-like state in EGF responsive cells, apparently through binding to the EGF receptor. It is interesting to speculate that sarcoma growth factor acts as a super-agonist on the EGF receptor, increasing the tyrosine phosphorylation activity of the EGF-stimulated kinase to levels seen in ASV transformation.

We thank Drs Tony Hunter and Bartholemew Sefton for helpful advice and gifts of ASV, anti-pp60^{src} serum and phosphoamino acid standards. The products of the highly polymorphic genes known as the major histocompatibility complex (MHC) have been shown to play a major part in the control of several aspects of the immune response and of susceptibility to certain diseases^{1,2}. The major transplantation antigens are membrane proteins composed of two noncovalently associated polypeptide chains: a light, non-polymorphic chain of molecular weight 12,000 (MW), called β_2 -microglobulin, and a polymorphic, glycosylated heavy chain of ~45,000 MW. The heavy chains in man and mouse are encoded in at least three loci of the MHC named HLA-A, -B and -C, and H-2D, K and L respectively. The available amino acid sequence data indicate extensive homology between human and mouse heavy chains^{3,4}. We therefore used a recently isolated cloned mouse H-2 cDNA probe⁵ to screen a human gene library. We have now characterized one of the recombinant phages obtained, λ HLA-12, and shown that it contains an authentic HLA sequence with evidence of a second one close by.

Major efforts have been directed towards the molecular cloning of HLA and H-2 gene sequences. The isolation of cloned cDNA copies has proved difficult because of the low abundance of the corresponding mRNAs *in vivo*. Nevertheless, cDNA clones carrying HLA⁶ and H-2 (ref. 5) sequences have been obtained. A recombinant plasmid, pH-2^{d-3}, recently isolated by Bregegere *et al.*⁷, carries a cDNA insert of 1,050 base pairs, which corresponds to the 3'-untranslated region (500 base pairs) and 550 base pairs of translated sequence of a mRNA coding for a H-2 heavy chain of the *d* haplotype. H-2 and HLA heavy chains consist of three globular domains followed by a transmembrane sequence which anchors the molecule at the cell surface, and a short intracellular carboxy-terminal fragment. pH-2^{d-3} lacks the sequences coding for the first two domains but contains the rest of the coding sequence.

Comparison of HLA-B7, HLA-A2 and H-2K^b amino acid sequences shows that the third domain is the best conserved part

Fig. 1 Ethidium bromide-stained gel (left) and autoradiogram after transfer and hybridization with the H2-1 (middle) or the H2-2 (right) probes of λ HLA-12 DNA digested with *Eco*RI, *Sst*I and *Sst*I + *Eco*RI restriction enzymes. The first pattern on the left is *Hind*III-digested λ DNA giving fragments at 23.6, 9.46, 6.78, 4.34, 2.26 and 1.98 kilobases. Aliquots of digested λ HLA-12 DNA were run on a 0.5% agarose gel slab (overnight at 3 V cm⁻¹) and transferred to nitrocellulose according to Southern¹¹. The filter was baked at 80 °C for 2 h, pretreated for 4 h at 68 °C in 6 × SSC, 1 × Denhardt's mix¹² and hybridized overnight at 68 °C in 2 × SSC, 1 × Denhardt, 0.5 × SDS with H2-1 or H2-2 probes. The probes (*Pst*I-digested pH-2^d-3 DNA fragments) were recovered from a low gelling point agarose gel¹³, run on a small DEAE (DE52) column and labelled by nick-translation¹⁴ to specific activities of 1–4 × 10⁷ d.p.m. per μ g. After hybridization, filters were washed three times at 68 °C in 2 × SSC, 1 × Denhardt and 0.5 × SDS, twice at 20 °C in 2 × SSC, 50% formamide, 0.5% SDS, and twice in 2 × SSC. Exposure was 1–2 days at –70 °C with Ilford 'fast tungstate' screens. It is apparent from these patterns (see Fig. 2 for corresponding restriction map) that the H2-1 probe hybridizes only to the right of the last *Sst*I site in the insert whereas the H2-2 probe hybridizes to two sets of fragments which are in fact separated by ~1.9 kilobases.

of the molecule^{3,4}; the H-2^d amino acid sequence derived from the pH-2^d-3 DNA sequence shows 72.6% homology with that of HLA-B7 in the third domain⁷. These observations led us to speculate that there might be sufficient nucleotide sequence homology between H-2 and HLA DNA sequences to allow specific hybridization of H-2 probes to human HLA genomic segments.

Two DNA fragments were purified from the pH-2^d-3 plasmid after digestion with *Pst*I: one (abbreviated H2-1) is ~600 base pairs long and includes sequences coding for the transmembrane and cytoplasmic parts of the H-2 heavy chain and the other, H2-2, is 195 base pairs long and encodes most of the third domain⁷. Both fragments were labelled with ³²P by nick-translation and used as probes to screen a human gene library consisting of random DNA fragments recombined in λ Charon 4A, constructed by Lawn *et al.*⁸. About 10⁵ plaques were screened and several positive phages were purified. *In situ* hybridization was initially carried out with probe H2-1 at 63 °C

in 2 × SSC (rather than the usual 68 °C). However, all positive phages hybridized strongly with probe H2-2 at 68 °C. One recombinant, λ HLA-12, containing a 15-kilobase insert, was selected for further study.

λ HLA-12 DNA was analysed by digestion with *Eco*RI, *Sst*I and *Bgl*II restriction enzymes alone or in combination. The fragments were separated on agarose gels and analysed by Southern blotting and hybridization with the H2-1 and H2-2 probes. Figure 1 shows an example of such an analysis. The restriction map obtained for λ HLA-12 is shown in Fig. 2. H2-2 hybridized to two different *Sst*I fragments, which indicates that at least one cleavage site may lie within sequences homologous to this (third domain-specific) probe; H2-1 hybridized only to the right-ward *Sst*I fragment. Hybridization to the *Bgl*II and *Bgl*II + *Sst*I fragments confirmed these results, which indicate that the gene is oriented left to right on the map.

As *Sst*I was suspected to cleave within the region coding for the third domain, λ HLA-12 DNA was digested with *Sst*I restriction enzyme and labelled at the 5' or at the 3' ends. One of the fragments hybridizing with the H2-2 probe (see Fig. 1) was isolated after secondary digestion with *Eco*RI restriction enzyme and sequenced by the Gilbert–Maxam method⁹; labelling at the 3' and 5' ends allowed sequence determination on both strands from the same restriction site.

The DNA sequence obtained to the left of the second *Sst*I site in the insert is shown in Fig. 3. The protein sequence corresponding to a translation phase open in this region is shown above the nucleotide sequence; the HLA-B7 (ref. 3) sequence is shown on top. Figure 3 shows that the region sequenced corresponds to an HLA gene segment (amino acids 199 to 230 in

Fig. 2 Restriction map (R = *Eco*RI, S = *Sst*I, B = *Bgl*II restriction enzymes) of λ HLA-12. λ HLA-12 was identified and purified by three successive rounds of plaque hybridizations¹⁵ (1 × 10⁴, 3 × 10³ and 200 plaques per dish) using nick-translated¹⁴ (1–3 × 10⁸ c.p.m. per μ g) H2-1 or H2-2 probes (for conditions see Fig. 1 legend). Autoradiography was overnight at –70 °C using flashed films and Du Pont 'Cronex lightning plus' screens. λ HLA-12 DNA was prepared from a 600-ml culture of the *Escherichia coli* 1106 strain infected at a multiplicity of three. The phage was purified on caesium chloride step and continuous gradients and DNA was extracted using phenol, ether and ethanol precipitated. For mapping purposes aliquots (0.5 μ g) of the DNA were digested with restriction enzyme(s) and analysed in parallel on 0.5% agarose gel slabs. Southern hybridizations¹¹ were done as described in Fig. 1 legend. Top, complete map including the Charon 4A λ phage¹⁶ (with the right arm to the left to show the insert in the correct orientation with respect to gene sequences). Bottom, enlargement of the region in which DNA sequencing was performed, the direction of transcription is shown by the arrow. The dashed line indicates the *Eco*RI–*Sst*I fragment hybridizing with H2-1, the dotted line those hybridizing with H2-2. The area whose sequence is given in Fig. 3 is indicated by the box; the corresponding region in the HLA-B7 protein sequence is shown below with the numbers of the terminal amino acids. The approximate position for the third *Sst*I site in the insert is indicated.

extracts were subjected to two-dimensional gel electrophoresis. Figure 1a, b shows autoradiograms of gels of bacteria infected with λ himA⁺ and λ himAam79, respectively. The two autoradiograms are equivalent except for the absence, in the gel of the λ himAam79-infected cells, of an 11,000-molecular weight (MW) spot that is present in the gel of bacteria infected with λ himA⁺. Gels of extracts of uninfected cells were devoid of labelled spots (data not shown). As nonsense mutations are known to cause premature polypeptide chain termination, the absence of this spot tentatively identifies this 11,000-MW protein (marked *himA* in Fig. 1a) as the product of the *himA* gene (*phimA*). No protein that could correspond to the *phimAam79* amber fragment is seen. Note that the *phimA* spot seems to exhibit charge heterogeneity in the isoelectric focusing dimension. The separation of two apparent species of *phimA* varies somewhat with the conditions of electrophoresis.

Further evidence supporting the identification of the 11,000-MW protein as *phimA* comes from an additional experiment detailed in Fig. 2. In this experiment, the dose of UV rays was insufficient to eliminate completely all host protein labelling and a small amount of label was incorporated into ribosomal protein S10 which therefore serves as a convenient reference point (see

below for the location of S10 in this gel system). As in the previous experiment, cells infected with λ himAam79 (Fig. 2a) lack the 11,000-MW *phimA* protein that is made after infection with λ himA⁺ (Fig. 2b). Furthermore, the λ himA42 transducing phage directs the synthesis of a protein of identical molecular weight to *phimA* but with a more basic charge. This suggests that the *himA42* mutation has substituted an amino acid in the *phimA* protein that results in a net basic charge shift.

From the results of the experiments discussed above, we identify *phimA* as an 11,000-MW protein. The position of this protein in the isoelectric focusing indicates that *phimA* is a weakly basic protein²⁸. We do not know whether the charge heterogeneity of *phimA* reflects the state of this protein within the cell.

The λ himA transducing phage directs the synthesis of several proteins in addition to *phimA*, most of which have previously been identified by Springer *et al.*¹⁷ and Henneke *et al.*^{18,19}. These workers used the same transducing phage in similar experiments, but analysed the labelled proteins by one-dimensional polyacrylamide gel electrophoresis. We were thus able to identify the spots in two-dimensional autoradiograms by comparing their apparent molecular weights and relative intensities. In Fig.

Fig. 1 Autoradiograms of two-dimensional gels of UV ray-irradiated lysogenic bacteria infected with λ himA⁺ (a) or λ himAam79 (b). Logarithmic phase cultures of strain K447 (159*uvrA*⁻ carrying λ c⁺ind⁺Nam7, 53) growing at 39 °C in M56 media²⁶ plus 0.2% maltose at a concentration of 2×10^8 ml⁻¹ were pelleted and resuspended at a concentration of 2×10^8 ml⁻¹ in M56 media. Cells (10 ml) were irradiated with 1.6×10^4 ergs mm⁻² of UV light from a GE germicidal lamp (~2 min at a distance of 10 cm), pelleted, resuspended to the same concentration in M56 with 0.02 M MgSO₄ and incubated in the dark for 15 min with shaking at 37 °C. To 0.5 ml of these cells, phage were added at a MOI of 10, and adsorption was allowed on ice for 15 min. The infected cells were once again pelleted and the supernatant discarded. To initiate growth, 2.5 ml of pre-warmed M56, 0.2% maltose and 0.02 M MgSO₄ were added and the cultures shaken at 37 °C in the dark. After 5 min, 10 μ Ci of ¹⁴C mixed amino acids (55 mCi mmol⁻¹, NEN) were added and labelling was allowed to continue for 60 min. The cells were then washed with cold 0.01 M Tris pH 7.4 and 0.01 M MgCl₂ and prepared for isoelectric focusing (IF). Strain K37 and the λ himA transducing phage are described by Miller and Friedman¹². Phage stocks were prepared by lytic growth in K37. Lysates were concentrated by polyethylene glycol precipitation²⁷ and purified by isopycnic CsCl buoyant density centrifugation. The phage were dialysed against 0.01 M Tris pH 7.4 and 0.01 M MgSO₄. Two-dimensional non-equilibrium gels were run according to the method of O'Farrell²⁸. All reagents and reagents are described in ref. 16. The IF dimension was run for 1,400 V-h using LKB ampholines (pH 3.5–10). The second dimension was a 20% polyacrylamide SDS stacking gel system with a 23-mm stacking gel and a 90-mm separating gel. Second dimensions were run for 5 h at 3.3 W per gel. The gels were stained in 0.005% Coomassie brilliant blue in 0.01% trichloroacetic acid, 7.5% acetic acid and destained in 7.5% acetic acid. Most of the ampholines could be removed by first soaking the gel in stain made 50% with ethanol. The gels were hot vacuum dried on Biorad paper and arbitrary orientation marks were drawn with radioactive india ink to facilitate subsequent alignment of the gel with the autoradiograms. The gels were then exposed to Kodak X-Omat film. Spot identifications are described in the text. The arrow in b indicates the expected location of *phimA*. Exposure time was 60 d. Samples were prepared for IF in the following manner. The labelled cultures were pelleted in 1.5-ml Eppendorf tubes; 100 μ l of 0.01 M Tris pH 7.4 and 0.01 M MgCl₂ containing 100 μ g ml⁻¹ freshly prepared lysozyme (Worthington) were added and the pellet resuspended. The cells were freeze-thawed for five cycles in an ethanol-dry ice bath. Aliquots of 5 μ l of a 1 mg ml⁻¹ solution each of pancreatic DNase (Worthington) and RNase (Sigma) were added and incubated on ice for 10 min. Then, 50 mg of solid urea (Schwarz-Mann ultrapure) and 100 μ l of lysis buffer¹⁶ were added to complete the sample preparation. The extracts were stored at -80 °C. The molecular weights of proteins were estimated by comparing the mobilities of the proteins in the second (SDS polyacrylamide) dimension with the mobilities of known proteins: two internal standards whose MWs are known from primary structure determinations were IF3 (20,668)²⁹ and whose location was determined in this work; and *E. coli* HU protein (9,535)³⁰, identified with purified HU protein (from K. Abremski). An additional marker was ribosomal protein S10 taken as 10,500 (refs 31, 32).

Fig. 2 Details of gels and autoradiograms of the regions surrounding S10 and IF3. *a-c*, UV-ray irradiated bacteria infected with λ himAam79 (*a*), λ himA⁺ (*b*) and λ himA42 (*c*). All three are autoradiograms. *d* Is the stained gel used to make the autoradiogram in *b* with the addition of purified IHF. *e* Is a composite overlay of *b* on *d*. Exposure time was 60 d. Purified integration host factor (IHF) was concentrated by precipitation with 20% trichloroacetic acid and resuspended in a 1:1 mixture of lysis buffer and 8 M urea.

1a, the spots are named for their respective genes. Thus, the spot marked *infC* is translation initiation factor IF3. As noted by Springer²⁰, the *infC* spot is the most heavily labelled and consists of a cluster of spots due to the different species of IF3²¹. We were able to locate the spot for IF3 in two-dimensional gels of total *E. coli* proteins by overlaying this autoradiogram on the stained gel. IF3 maps at coordinates (42, 54) on the standard non-equilibrium two-dimensional gel map of *E. coli* proteins of Bloch *et al.*²². The spots marked *thrS* (threonyl-tRNA synthetase), and *pheS* and *pheT* (the α - and β -subunits of phenylalanyl-tRNA synthetase) are also shown (the *pheT* spot does not resolve well in this system). Two additional spots have been identified as the products of the λ cI857 (repressor) and *rex* genes. These proteins, which are the only λ proteins synthesized in a repressed lysogen, were identified in separate experiments using non-transducing λ phage (H.I.M., in preparation).

Springer *et al.*¹⁷ have reported the presence of a fifth protein, p12, that they could not associate with a known gene. We have also found this protein in one-dimensional gels of our extracts. It is not *phimA* as it does not disappear when λ himAam79 is used for infection. (We were unable to detect *phimA* in the one-dimensional system, presumably due to the high background found in the region where *phimA* should migrate.) Furthermore, the p12 band does not resolve into a distinct protein spot in two-dimensional gels, indicating that it may not constitute a unique protein species as suggested by Hennecke *et al.*¹⁸.

The *E. coli* component required for integrative recombination has been extensively purified (H. A. N. and C. Robertson, in preparation). This protein (IHF) was assayed by its ability to complement purified Int protein²³ for *in vitro* recombination. The most highly purified material contains two polypeptides, and available evidence indicates that both are required for recombination activity. In the experiment shown in Fig. 3, 5 μ g of purified protein (fraction V) was mixed with a small amount of ¹⁴C-labelled total *E. coli* proteins (as reference proteins). Figure 3a shows the stained gel, *b* the autoradiogram and *c* a composite overlay of the autoradiogram and the stained gel. As shown in Fig. 3a, purified integration host factor (IHF) consists of two polypeptide species of molecular weights 11,000 (α , marked *himA*) and 9,500 (β , arrow). Both species exhibit apparent

charge heterogeneities in this gel system. The intensity of staining indicates an approximately equal molar amount of α and β . Note that the position of the 11,000-MW spot roughly corresponds to the position of *phimA* in Fig. 1a. In addition, both *phimA* and α exhibit similar patterns of heterogeneity.

Figure 3b shows the location of total *E. coli* protein labelled with ¹⁴C mixed amino acids. We have indicated the location of two reference proteins, IF3 (marked *infC*, see above) and ribosomal protein S10²². Note in Fig. 3b that although neither subunit is present in detectable quantities, S10 is positioned between the α - and β -subunits of IHF. Figure 2b, *d*, *e* shows the results of an experiment in which purified IHF was mixed with radiolabelled *phimA* (from a UV-ray irradiation experiment) and the mixture was subjected to gel electrophoresis. Only details of gels including the regions surrounding IF3 and S10 are shown. Figure 2d shows the stained gel, *b* the autoradiogram and *e* the composite overlay. The additional spots seen in Fig. 2d and *e* are unlabelled *E. coli* proteins derived from the extracts of the UV-ray irradiated bacteria. The radiolabelled *phimA* protein co-migrates with the purified α -subunits of IHF.

Thus, the *himA* genes codes for one of the subunits of IHF active in integrative recombination by λ DNA *in vitro*. This result fully explains the fact that strains mutant in the *himA* gene lack an active integration host factor and also eliminates the possibility that the *himA* gene influences λ integration solely at the level of synthesis of components of the recombinational apparatus. The demonstration that *phimA* is directly involved in integrative recombination has gained considerable importance in light of the recent finding that the *himA* gene also regulates λ integration at the level of synthesis of Int protein¹⁴. A feature of the transposon Tn3-encoded *tnpR* gene product is its involvement both in recombination and in control of transcription of transposon genes^{24,25}. Thus, dual function of site-specific recombination proteins may be a common characteristic.

The *E. coli* gene coding for the β -subunit of IHF has not been determined, although several candidates are available⁹ (H.I.M., in preparation). However, one or more of these gene products may be involved indirectly by regulating the synthesis or processing of either of the active subunits of IHF.

The fact that *phimA* is directly involved in recombination raises the possibility that *phimA* might also directly participate

Fig. 3 Two-dimensional gel of purified integration host component. *a*, Coomassie blue stained gel. *b*, Autoradiogram of ^{14}C -labelled total *E. coli* proteins added as internal markers. *c*, Composite overlay of autoradiogram and stained gel. Additional spots in *a* are due to added *E. coli* proteins. Exposure was for 10 days. Dark staining material in bottom right of *a* is residual ampholines. For labelling bacterial cultures, $10\ \mu\text{Ci}$ of ^{14}C mixed amino acids were added to a logarithmic phase culture at a cell density of $2 \times 10^8\ \text{ml}^{-1}$ in M56 media and 0.2% glucose. After 2 min at 37°C , $100\ \mu\text{l}$ of 30% cassamino acid solution was added to the 2-ml culture and the cells were prepared for isoelectric focusing.

in several diverse processes known to be influenced by *himA* mutations, such as the growth of bacteriophage Mu and the precise excision of transposable antibiotic resistance elements. The availability of purified IHF should facilitate the biochemical investigation of these processes.

We thank Dr M. Belfort for the UV-ray irradiation procedure, M. Smith for introducing us to non-equilibrium gels, R. Steinberg for photographic displays, Drs S. Adhya, D. Court, D. Friedman and B. Paterson for encouragement and advice, H. Echols for critical reading of this manuscript, and Carolyn Walker for preparation of the manuscript. This work was supported by grants GM-17078 and 5T32-GM0727 from the National Institute of General Medical Sciences to H. Echols.

A non-disruptive technique for loading calcium buffers and indicators into cells

R. Y. Tsien

Physiological Laboratory, University of Cambridge, Cambridge CB2 3EG, UK

Present methods for measuring or buffering intracellular free calcium concentrations are almost entirely limited to robust and well anchored cells which can tolerate insertion of ion-selective microelectrodes or microinjection of calcium indicators or buffers into one cell at a time¹. A very few types of small cells can be loaded with buffers or indicators during controlled lysis²⁻⁴, but such procedures grossly perturb membrane integrity and soluble cytoplasmic constituents. Liposome fusion releases only trace quantities of the trapped solute into the cytoplasm^{5,6} and incorporates foreign lipid into the target cell membranes. I now describe a simple technique which loads Ca^{2+} -selective chelators into the cytoplasm of intact cells in suspension and avoids the disadvantages of previous methods. The chelators are made temporarily membrane permeable by masking their four carboxylates with special esterifying groups which then hydrolyse inside the cells, regenerating and trapping the original chelators. The method is demonstrated on red cells, mast cells and lymphocytes.

The Ca^{2+} -specific chelator used in initial trials (shown in Fig 1a) is a member of a homologous family^{7,8} of buffers and optical indicators that have unusual specificity for Ca^{2+} over Mg^{2+} , H^+ , Na^+ and K^+ . Its affinity constant for Ca^{2+} is $\sim 10^7 \text{ mol}^{-1}$, other members of the family offer both higher and lower affinities. The simplest esters (methyl or ethyl) of this chelator are not hydrolysed in human erythrocytes. Anhydrides, imidazolidines, or activated aryl esters were rejected because the end products would probably include chelator molecules irreversibly bound to intracellular nucleophiles. Trimethylsilyl esters were too rapidly hydrolysed extracellularly, while *t*-butyldimethylsilyl esters were potentially haemolytic. Success was finally achieved with the acetoxymethyl tetraester (Fig 1b), analogous acyloxy-alkyl esters are used to enhance intestinal absorption of antibiotics^{9,10}, and the accepted mechanism of hydrolysis is enzymatic cleavage of the acetyl ester linkage, followed by rapid spontaneous release of formaldehyde. Acetyl esterases are present in many cell types, as suggested by their ability to hydrolyse fluorescein diacetate^{11,12}.

The acetoxymethyl ester (Fig 1b) was prepared by dissolving the chelator free acid, 5 equivalents of dry ethyldisopropylamine (redistilled from reagent supplied by Aldrich Chemicals) and 6 equivalents of acetoxymethyl bromide¹³ in ethanol-free chloroform. After stirring for 24 h at room temperature, the solution was evaporated under vacuum and the residue dissolved in benzene, filtered to remove amine salts, and re-evaporated. Extraction of this residue with ether, followed by evaporation, yielded a soft gum which was largely but not entirely pure as determined by PMR spectroscopy. Solutions or

Fig. 1 Structures of the calcium chelator (a) and its acetoxymethyl tetraester (b). Hydrolysis of the ester should yield the chelator tetra-anion, four molecules each of acetate and formaldehyde, and eight protons.

Fig. 2 Ability of intracellular chelator to delay the onset of the Ca^{2+} -induced K^+ permeability caused by A23187 (added as indicated to a final concentration of 200 nM). Abscissa, time, ordinate, fluorescence from 250 nM of the voltage-sensitive dye diS-C₃(5)^{18,19} in a suspension (0.04% haematocrit) of either normal human red cells (broken line) or cells loaded with chelator as described in the text (solid line). Fluorescence (excitation $630 \pm 10 \text{ nm}$, emission $665 \pm 10 \text{ nm}$) is expressed as a percentage of that seen in the absence of cells. The medium contained 130 mM NaCl, 10 mM KCl, 0.1 mM CaCl_2 and 10 mM tris(hydroxymethyl)-aminomethane-morpholinopropanesulphonate, pH 7.4, 22°C. Decreased dye fluorescence indicated membrane hyperpolarization due to increased K^+ permeability, resulting from increased $[\text{Ca}^{2+}]$. Ester treatment was followed by sufficient washing to remove essentially all acetate and formaldehyde. The low concentration of A23187 was adequate to induce K^+ permeability because of the absence of Mg^{2+} from the medium¹⁵. At an external $[\text{K}^+]$ of 10 mM, the effect of the dye on K^+ permeability may be disregarded¹⁷.

suspensions of the ester in physiological saline were prepared by injecting freshly made-up concentrated stock solutions in dimethyl sulphoxide into well stirred aqueous solutions.

Human erythrocytes were used in initial trials as they are readily available in large numbers, lack internal Ca^{2+} -sequestering organelles and proteins, and have a well characterized Ca^{2+} -triggered K^+ permeability. The low rate of endogenous H^+ production and the rapidity of transmembrane pH equilibration allow ester hydrolysis to be monitored by H^+ production in a pH-stat. There was no ester hydrolysis detected at neutral pH in the absence of cells, but with cells at 10% haematocrit, pH 7.4, 37°C, the partially purified ester (0.2 mg per ml of suspension) released protons at a rate decaying roughly exponentially with a time constant of $\sim 15 \text{ min}$. After 2 h, total acid production, corrected for endogenous H^+ production, was 1.56 mM, slightly more than expected from complete hydrolysis of perfectly pure ester. Cell lysis after 2 h was 5.5%, partly due to the continued vigorous stirring necessary in a pH-stat. Titration of an aliquot of the cell suspension with CaCl_2 and a Ca^{2+} -selective electrode¹⁴ showed that the amount of chelator accessible to the extracellular space was only $\sim 3\%$ of that expected from total ester hydrolysis. About this amount would be expected just from haemolysis during the loading procedure. However, once the cells were lysed by freezing and thawing, titration revealed $\sim 1.4 \text{ mmol}$ chelator per litre of cells ($\sim 90\%$ yield) with the correct Ca^{2+} affinity, within experimental uncertainty imposed by incomplete Ca^{2+} selectivity of the electrode at $p\text{Ca} \geq 7$. The amount of intracellular chelator did not significantly change either after resuspension of the loaded cells in chelator-free saline for 1 day, or after digestion with 0.1 M KOH for 2 days, showing that the chelator was well trapped and that hydrolysis was complete. Imperfect purity of the ester gum was probably a major reason why the yields of protons and chelator were not quite stoichiometric.

Fig. 3 Dose-response curve showing the ability of intracellular chelator to counteract the stimulation of histamine secretion from rat peritoneal mast cells by Con A plus lysophosphatidylserine. The cells were obtained and purified as described elsewhere²¹. The lysolipid was a gift of Dr G. A. Smith. The abscissa indicates the concentration of ester in which each batch of cells (10^5 per 25 μ l) was incubated for 30 min at 25 °C. The cell suspensions were then diluted to 500 μ l each, stimulated with Con A and lysolipid (final concentrations 100 μ g ml⁻¹ and 1 μ M respectively) for 15 min, and assayed for histamine release²¹. The ordinate indicates histamine release (corrected for spontaneous release) as a percentage of the stimulated histamine release in the absence of ester. This percentage is negative for ester concentrations ≥ 100 μ M because cells thus treated released less histamine after stimulation than the 'spontaneous release' controls that were neither stimulated nor treated with ester. Circles and squares represent two independent experiments in which spontaneous histamine release was, respectively, 2.9 and 5.0% of total cell histamine, and stimulation without ester gave releases of 23.6 and 11.0%. Control experiments showed that the inhibition by ester was not due to formaldehyde or acetate, as preincubation with up to 400 μ M formaldehyde (as would be produced by complete hydrolysis of 100 μ M ester) or 4 mM acetate showed either no effect on, or an actual enhancement of, stimulated histamine secretion.

Figure 2 shows an independent demonstration that these cells have trapped a cytoplasmic high-affinity Ca^{2+} chelator. In normal cells (broken line), addition of the Ca^{2+} ionophore A23187 causes an influx of Ca^{2+} , increasing the intracellular free calcium concentration ($[\text{Ca}^{2+}]_i$) and switching on a K^+ permeability^{2,15,16}. In medium containing 10 mM K^+ (ref. 17), this permeability hyperpolarizes the cells and can be detected as the decrease in fluorescence (ordinate) of a membrane potential-sensitive dye^{18,19}. Introduction of an intracellular Ca^{2+} chelator should mean that the Ca^{2+} influx has to continue much longer before the threshold $[\text{Ca}^{2+}]_i$ is reached. As expected, the ester-treated cells (solid line) show a marked delay before hyperpolarization develops, presumably reflecting the time required for the Ca^{2+} influx to titrate the trapped buffer.

Another cell type that accumulates chelator is the rat peritoneal mast cell, but the small number of cells and their internal complexity made use of the pH-stat and direct Ca^{2+} titrations impractical. Instead, chelator uptake was qualitatively assessed by the inhibition of $[\text{Ca}^{2+}]_i$ -dependent histamine release²⁰. Figure 3 shows that preincubation of mast cells with increasing concentrations of the ester progressively inhibited histamine release in response to concanavalin A (Con A) plus lysophosphatidylserine^{21,22}. Preincubation with ester was also able to stave off the normally immediate release of histamine induced by a moderate dose of A23187. However, higher concentrations of the ionophore or longer exposure times eventually overcame this inhibition and led to the release of most of the cellular histamine. Thus the effect of preincubation with ester is consistent neither with a blockage of Con A-induced Ca^{2+} permeability, nor with permanent fixation of the histamine granules or metabolic poisoning, but can be explained by a fixed quantity of high-affinity chelator preventing or delaying the rise of $[\text{Ca}^{2+}]_i$ to the threshold for secretion. No toxic effects have yet been

detected in red blood cells or mast cells from the formaldehyde which should be released by the hydrolysis of effective concentrations (up to several hundred μ M) of ester. This is probably because the high permeability of formaldehyde and the low cytotoxicity prevent its concentration exceeding millimolar amounts anywhere. Histological fixative concentrations are of the order of hundreds of millimolar, whereas for short-term exposures to several millimolar, mild and partially reversible pharmacological effects are reported^{23,24}. If formaldehyde toxicity presents difficulties, it should be possible to change the acyloxy-alkyl group to release alternative carbonyl compounds^{9,10}.

These experiments show how chelators trapped by ester hydrolysis can damp out short-term $[\text{Ca}^{2+}]_i$ transients and thus reveal qualitatively which cell functions are influenced by such transients. The method described here can be greatly extended by choosing a chelator which is also a sensitive optical indicator of $[\text{Ca}^{2+}]_i$. For example, a fluorescent methoxyquinoline (structure 3b of ref. 7) is readily trapped inside mouse thymocytes and pig mixed lymphocytes by its acetoxymethyl ester²⁵. At low indicator dose, the Ca^{2+} sensitivity of its fluorescence⁷ shows that resting $[\text{Ca}^{2+}]_i$ in lymphocytes is 123 ± 6 nM ($\pm$ s.e.m., $n = 27$), a much sought-after²⁶ but hitherto unmeasured value. Higher intracellular concentrations of chelator, up to at least 4.7 mM, are also easily attained by adjustment of cytochrome and initial ester concentration. Effects of such buffering dosages on capping and mitogenic stimulation are being studied, the fluorescence sensitivity allows quantification of the effectiveness of the buffer in damping changes in $[\text{Ca}^{2+}]_i$.

Intracellularly hydrolysable esters offer the first method for trapping membrane-impermeable chelators and indicators inside large populations of small intact cells without disrupting their membranes. A technically simple and reliable new approach to the measurement and control of $[\text{Ca}^{2+}]_i$, thus becomes possible. All cell types tested so far have proved able to accumulate significant amounts of chelator. As this technique has been shown to give the expected results in cell types where the role of intracellular Ca^{2+} is fairly well understood, it can now be applied with greater confidence to a wide variety of tissues where the function of Ca^{2+} is less well established. Analogous esters may also prove useful outside the field of Ca^{2+} function, for example to deliver and trap indicators of pH and free Mg^{2+} , chelators of toxic heavy metals, or other membrane-impermeable carboxylic acids.

I thank the SRC for financial support and T. J. Rink, V. L. Lew and G. A. Smith for helpful discussion.

BOOK REVIEWS

Memories of the secret city

Rudolf Peierls

Los Alamos was the laboratory set up, during the Second World War, to design and produce atomic bombs from the fissile materials, uranium 235 and plutonium, provided by the gigantic installations of the "Manhattan District" of the US Army. A remote location in the hills of New Mexico was chosen partly because of the high degree of secrecy required, and partly because the work might involve hazardous experiments. Conceived originally as a settlement for 265 people — six scientists with their support staff and families — it had grown to many thousands by the end of the War, largely because the design of a plutonium bomb proved much more difficult than had been foreseen.

Much has been written about the achievement of the laboratory in solving the difficult technical problems so quickly, and about the life in this unusual community. The present collection of lectures, given at Santa Barbara in 1975, is a most interesting addition to this literature, containing the recollections of scientists, of scientists' wives and of an army officer.

Imagine a team of scientists, many of them at the top of their professions, working in improvised buildings, living in temporary housing, depending for their professional and domestic needs on the army, and subject to security restrictions they did not always see as necessary or consistent, imagine a collection of army personnel supporting the activities of scientists whose objectives they were not supposed to know, and whose methods and manners were quite foreign to the army's style of operation. There were bound to be conflicts, irritations and grievances. The recollections indeed include many examples of such friction. The fact that all major problems were somehow resolved, and the minor nuisances accepted, is a tribute to the good sense of the people involved, their feeling of urgency and in no small measure to the personality of the director, Robert Oppenheimer.

There is already some folklore about the place. The first lecture, by General Dudley, reports four versions of how Los Alamos came to be selected as the site of the laboratory — his own and three others — of which at least two are quite incompatible with his and with each other. The recollections of the residents do not show any such disagreements on facts, but they differ much in emphasis. Some seem to remember above all the irritations, the shortages, the beautiful school building which for a time had no qualified teachers, the strange facets of the voluntary mail

Reminiscences of Los Alamos, 1943–1945
Edited by Lawrence Badash, Joseph O Hirschfelder and Herbert P Broida Pp 188
(Reidel 1980) Hbk Dfl 50, pbk Dfl 20

censorship. Others stress the attractions of the landscape and climate, the contacts with the local Indian culture, and above all the proximity of a large number of unusually gifted and interesting people. But all would probably agree with Laura Fermi's remark:

One interesting thing to me is that during the war I was in Los Alamos only a year and a half, and *still* it seems such a big portion of my life. It was so different, it was such intense living, that it seems impossible that in my case it actually lasted hardly eighteen months.

Her account and those of Bernice Brode and Elsie MacMillan give a lively picture of the domestic scene. Feynman's "Los Alamos from Below" is as entertaining as one has come to expect from him. He reveals the secret of his notorious skill in opening combination locks, and how he accidentally stumbled on a safety hazard in a complicated plant design. There are hilarious accounts of his brushes with the censor and other bureaucratic elements. In stressing his "low" status he has his tongue in his cheek. He was recognized at once as a man of outstanding promise. The opening statement that he did not even have a degree, has to be withdrawn a little later when he admits that he did complete his PhD before going to Los Alamos.

Kistiakowsky's reminiscences form the most substantial part of the book. He

describes, in non-technical language, the work of his division in designing and making the "implosion" device. He and his collaborators, whose contributions are individually acknowledged, had to fight on two fronts: against professional engineers who insisted on using traditional methods for unprecedented problems, and against physicists who wanted to verify the functioning of the devices by clever, but ambitious and time-consuming, and not always reliable, tests. His lecture ends with a disarmingly frank account of how he had a little too much drink in celebrating VJ Day, and how he fired 21 high-explosive bursts in place of a 21-gun salute, only it came out to be 22.

John Manley and Edwin MacMillan describe the early stages in the creation of the laboratory. Joseph Hirschfelder contributes a brief outline of the work of the laboratory with thumbnail sketches of some of its most famous members. Norris Bradbury, director from 1945 to 1970, deals with the transition to a peacetime institution. There is a historical introduction by Lawrence Badash.

A few questions after each talk give the impression that the audience (or at least its more vocal members) followed the lectures less intelligently than the reader will, but they still elicited interesting answers.

All in all, this mixture of styles and approaches adds up to a lively picture of an unusual, and maybe unique, experience. □

One man's view of desertification

Peter D. Moore

Land, Man, and Sand. By James Walls Pp.336 (Macmillan, New York/Collier Macmillan, London 1980) \$19.95, £12.95

"WHAT? Not *another* world conference?" Barbara Ward exclaimed in *The Economist* on hearing of the proposed United Nations Conference on Desertification in 1977. "What? Not *another* book reporting the outcome of another world conference", we may be forgiven for retorting on being faced with *Land, Man, and Sand*, a summary of the Desertification Conference's findings.

It is, however, a slightly different approach to the need for disseminating the results of such conferences in that it is

written by a single author, and he an experienced writer. Instead of being presented with an uncoordinated, turgid set of papers, we have a unified, flowing account which draws liberally upon the original reports and documents. It is an interesting experiment in communication, the main disadvantage of which is that we are inevitably given one man's viewpoint, however fair and objective that man may attempt to be.

If there is one thing more boring than collections of conference reports, it is accounts of how conferences come to be convened. No doubt much thoughtful, bureaucratic effort goes into this area of scientific communication but, generally

speaking, it lacks the glamour or even scientific content which warrant an introductory chapter. The only vital information within it is that the core of the conference was to be comprised of 15 case studies of desert-spread research from widely separated parts of the world. It is these studies which have formed the basis for the remainder of this book.

There are two aspects of the character of James Walls which emerge from these chapters and which demand comment. The first is that he handles language skilfully, though some of his descriptive passages would be more appropriate in a novel than in a supposedly scientific text. The second is that he is eager to comment upon rather than simply to paraphrase the reports which form the basis for the book. His comments are generally critical, incisive, voluble and often completely lacking in any factual basis. He is a master of emotive writing and selective editing.

There is a danger here of falling into the same trap, so I will confine my specific comments to the one case study in which I have had first-hand experience, namely the Turan study of north-east Iran. Walls' report of this study contains a regular smattering of factual errors. He constantly equates the modern town of Shahroud with the Parthian capital Hecatompylos, more important, his reproduced maps confuse areas of moving sands with the saline plains, thus making a nonsense of subsequent discussion of the geography

and sociological effects of sand movements.

It is this kind of betrayal of his lack of knowledge of the places and the people in this study which leads one to take with a pinch of gypsum his hostile comments about the sociological base of the study. For example, the statement is made in the case study that the traditional pastoralist of Turan is concerned more with the condition of his animals than with that of the vegetation. This conclusion is regarded as vapid and patronizing by Walls. How he can level such criticisms without the necessary experience is difficult to discern. The sociologist/anthropologists involved in this study spent many months living with the people of Turan and spoke fluent Farsi. I would prefer to trust their judgement on the issue than the preconceptions voiced by the commentator.

Sadly, the book exhibits many such examples of the author expressing his opinion in areas where it is unlikely that he has experience to equal the originators of the case study reports. These reports incidentally, are available in complete form, free from editorial comment (held by the United Nations Environmental Programme) and I would strongly recommend interested parties to seek these for information rather than this book. □

Who's playing games?

Lindon J. Eaves

The IQ Game: A Methodological Inquiry into the Heredity-Environment Controversy By Howard F Taylor Pp 276 (Harvester/Rutgers University Press 1980) £18.95, \$19.50

The IQ Game arises from the author's "Sincere concern with the accurate assessment of the causes of variation in IQ." It is a detailed development of three principal criticisms of past research into the genetic basis of intelligence. The author's concern primarily with "heritability" and "IQ" may have limited his opportunity to explore in detail many other relevant aspects of research and theory in the general area of human quantitative genetics.

Dr Taylor's first two arguments have a familiar flavour to those who have followed the discussions of the past 15 years: (i) data are inadequate, (ii) parameters estimated from only one or two kinship correlations may be biased. The third main theme is an assault on the case where it is strongest — in the work of the path analytic and biometrical genetical schools whose long campaign to raise the standard of debate in the area is at last bearing fruit. Even here, where large numbers of kinship correlations are examined simultaneously with explicit models and statistical tests, the author suggests that the possibility of a very substantial environmental component cannot be excluded. In developing this position he relies heavily on a single model for the genetic and social transmission of intelligence suggested early in the 1970s by Morton and his associates, with its peculiarly idiosyncratic assumptions about the mating system and environmental transmission. The book depends also on the cogent criticisms and corrections of Professor Goldberger. It is convenient to have these reviewed in a more accessible form.

Dr Taylor shows that the remarkable consistency of multiple kinship data with a simple model for genetic and social transmission might be improved still further by the inclusion of numerous additional "environmental" components to explain anomalies in the data. Taken to the limit, indeed, it is possible to dispense entirely with a genetic component by recourse to as many *ad hoc* environmental parameters as there are kinship correlations to be explained. Those who play the "IQ game", according to Dr Taylor, make such arbitrary and implausible assumptions as will secure an estimate of heritability. This leads to the claim that a "plausible" relaxation of assumptions would reduce the estimated contribution of genetic factors and justify complete agnosticism about the causes of individual differences. In his analysis, however, relaxation of

James D. Watson THE DOUBLE HELIX

A NEW CRITICAL EDITION

Edited by Gunther S. Stent

The discovery in 1953 of the structure of DNA transformed the science of biochemistry. Written by one of the participants in this exciting scientific advance, *The Double Helix* has sold over a million copies since its publication thirteen years ago.

In this new critical edition the original text is accompanied by the reviews by leading scientists which greeted its publication, retrospective views of two other chief characters in the story — Francis Crick and Linus Pauling — and the original scientific papers in which the double helical structure of DNA was presented.

£10.00 ON SALE NOW

Weidenfeld & Nicolson

assumptions is not accompanied by any reduction in residual degrees of freedom. He is thus proceeding as if *any* set of environmental correlations is equally appealing.

It is here that the author's basic misconception of the "game" is revealed. However much the assumptions of the Hawaii model might be questioned on biological or psychological grounds, they are nevertheless founded upon a strong yet simple theory of genetic and social transmission. Such a theory comes close to predicting the observed distribution of individual differences in IQ. Science only degenerates into a "game" when additional components are imported *post hoc* with no clear basis in a theory of gene action or social interaction.

The provision of competing environmental theories which could match the classical genetic theory for simplicity and explanatory power is an exciting and challenging prospect. The book devotes three pages to a number of positive suggestions, of which the need to develop

environmental theories is but one. It is suggested that IQ should be treated as an index of an underlying construct rather than the actual phenotype of interest, that models for multiple cognitive measures be developed, that models and designs should be explored to allow separation of the developmental recursion of genetic and environmental factors.

Had these suggestions been published at the start of the past decade they would have been heralded as a positive and imaginative contribution. Now, however, Dr Taylor is not alone in his concern for truth. A substantial body of theoretical and empirical research in the wider area of human and behavioural genetics has been published in journals and conference proceedings. Over the past five years a significant start has been made on the study of precisely these issues and in response to those criticisms that the book develops in such detail. □

How microorganisms get their nitrogen

Ben Mifflin

Microorganisms and Nitrogen Sources: Transport and Utilization of Amino Acids, Peptides, Proteins, and Related Substrates. Edited by J. W. Payne. Pp 870. (Wiley 1980) £45, \$126.60.

THE lengthy sub-title of this book is intended, according to the editor, to provide a more complete indication of the coverage of the volume. However, even this does not really do justice to the number of topics covered. For example, at least four of the chapters deal with some aspect of nitrogen metabolism in higher plants, one of which is entirely devoted to the subject. Further, although the book set out to cover transmembrane metabolism, it also deals in some detail with the utilization of ammonia, amino acids and peptides. In all there are nearly 900 pages, spread over 26 contributions which are divided into four sections: Amino Acids, Peptides, Proteins, Related Systems. These have been written by a variety of international authors, many prominent in their field. Six chapters cover the transport and utilization of amino acids and peptides in bacteria, yeast and fungi. The genetics, regulation and energetics of the uptake of these nitrogen sources are dealt with separately in a further six chapters. Reflecting our greater knowledge of bacterial biochemistry, relative to that of other organisms, there is discussion of the membrane proteins responsible for amino acid transport. The section on proteins, although still dealing with transport, is more heavily biased towards utilization and re-utilization.

The final section of the book is to me what makes it really worthwhile, it is unusual in that the editor has included a number of contributions that should encourage the readers to broaden their horizons. Thus, there is a chapter on the γ -glutamyl cycle in animals and speculation as to how it might apply to microorganisms, and two on the utilization of nitrogenous compounds by green autotrophic plants. The utilization of ammonia and amides is well covered in three contributions and the reader is finally informed of some of the other functions of peptides, notably as antimicrobial agents and ionophores.

The contributions have generally been written with the aim of making them a readable and developmental account of the field rather than a combination of the author's latest results and his reference card library which, alas, all too often occurs in multi-authored volumes. The coverage of the literature is generally broad although not exhaustive (or exhausting) and, considering the size and number of authors, is reasonably up to date.

Whilst it is possible to argue with various points expressed and to pick out certain mistakes, this would be ungenerous to an editor and authors who have obviously striven hard to provide an informative and stimulating book, which I am sure will be a standard work in the field for many years to come. □

Complexity of melting

G. Gee

Crystal Melting. Macromolecular Physics, Vol 3. By Bernhard Wunderlich. Pp 363. (Academic 1980) \$42.50, £23.80.

THIS volume, the third in the author's treatise *Macromolecular Physics*, adds three chapters to the seven already published (in 1973 and 1976). The three volumes deal successively with the description of macromolecular crystals, with their growth and now with their melting. Although the author states that the first part of the project is now complete the next volume is evidently planned in some detail, for there are numerous references forward to it for thermodynamic discussions which are needed in this volume. This spreading of intimately interconnected topics over four volumes and ten years is a necessary consequence of a single author undertaking such a huge task, but it is not very helpful to today's reader to be told (p. 104) "the derivation is obvious by comparison with the results listed in 11.2.3" (Vol. 4).

In any elementary thermodynamics course melting is presented as a simple example of equilibrium between two bulk phases: a perfect crystal and its melt. Why then a whole volume on melting? In the first place, polymer crystals are characteristically small and imperfect. 100 per cent crystallinity is seldom attainable. Even the "melt" may require further specification, for example molecular weight and perhaps cross-linking or (in copolymers) composition. Finally, equilibrium between the two is in most cases almost impossible to achieve. These problems are recognized in the chapter divisions: equilibrium melting, irreversible melting, copolymer and isomer melting. In each chapter a discussion of general principles is followed by a detailed and critical survey of what is considered to be the most important and reliable experimental work.

This volume, like its predecessors, is addressed primarily to the specialist reader. He can safely be assumed to have at least a general knowledge of the topics discussed in other volumes (including those yet to appear). For him it is a splendid book, a reliable guide to the literature, offering a considered judgement but quick to point out difficulties. It is altogether too detailed for a reader wanting only a general account of this aspect of polymer physics. Between the two extremes will be many, engaged perhaps in the making or application of polymers, who will find it a useful source of reference and comment on the behaviour of a particular material. □

The second edition of Gregory Bateson's *Naven*, the classic study of the culture of the Iatmul people of New Guinea, has been reissued by Wildwood House, price £4.50.

Aspects of the oceanography of shelf seas

Henry Charnock

The North-West European Shelf Seas The Sea Bed and the Sea in Motion. Vol II, Physical and Chemical Oceanography, and Physical Resources Edited by F T Banner, M B Collins and K S Massie Pp 337 (Elsevier Scientific 1980) Dfl 185, \$90.25

IN THIS addition to the Elsevier Oceanography Series, five specialists deal with the tides, the wave climatology and with the physical oceanography of the Irish Sea, the North Sea, and the Celtic Sea and English Channel. One chapter deals with tidal power and a further seven are devoted to trace metals, to artificial radioisotopes, to sediment transport and to chemical and seabed resources (other than hydrocarbons). Volume I of this two-volume set dealt with the geology and sedimentology of the same area.

The physical oceanography contributions (Irish Sea by Bowden, Celtic Sea and English Channel by Pingree, and North Sea by Lee) are complementary, treating the same types of phenomena from different points of view. Coastal oceanography is clearly more complicated, if not more difficult, than that of the deep ocean conditions are much less homogeneous so that it is difficult to study idealized processes. But the economic and aesthetic

importance of some of the problems has led to an increase in the effort being put into trying to solve them. The numerical model succinctly described by Pingree should prove an increasingly valuable tool. Similar models are referred to by Huntley in his scholarly chapter on tides.

Of the other chapters, those on wave climatology (Draper), trace metals (Burton, Young) and artificial radioisotopes (Mauchline) are essentially factual. It is especially in these chapters that the delay between the preparation of the book and its publication is to be regretted, new measurements are being made, and old results updated, at a gratifyingly rapid rate.

Contributions on sediment transport and seabed resources (both by Banner) and the extraction of inorganic materials (Massie) illustrate the possibilities for exploitation of the ocean. They should be read in the context of the other chapters and in particular with that on socio-

economic development and the management of coastal zones, by Harding, which gives a good account of how difficult it is to use the ocean wisely, even (especially?) in a confined region bounded by developed nations. The north-west European shelf seas (and perhaps especially the North Sea) represent a microcosm of what is increasingly recognized as a global problem of the future.

Since this region is one of the relatively few with large tidal range, it was perhaps sensible to include a chapter on tidal power (by Wilson). This gives a clear account of the Rance Scheme, of the USSR experience and of the UK prospects, but could be better appreciated if there was a related account of wave energy, and perhaps of wind power.

There is, one supposes, rather little in this book which could not be found elsewhere, but it is convenient to have the material gathered together into one volume. □

Henry Charnock is Professor of Physical Oceanography at the University of Southampton

Mycotoxin biosynthesis reviewed

E. Arthur Bell

The Biosynthesis of Mycotoxins A Study in Secondary Metabolism Edited by Pieter S Steyn Pp 432 (Academic 1980) \$44, \$24.80

WIDESPREAD interest in the mycotoxins dates from the discovery of the aflatoxins in the early 1960s. Since then much has been published on these compounds and, as Sir Derek Barton states in his foreword to this volume, "the time is certainly ripe for an authoritative book". The present "authoritative book" is a collection of chapters written by leading workers in the field.

In the first chapter Bu'Lock discusses mycotoxins as secondary metabolites derived variously from polyketides, peptides, terpenes and other precursors. He emphasizes, moreover, that secondary metabolism, including mycotoxin biosynthesis, can be affected dramatically not only by the genetic modification of a fungus but also by the conditions under which the organism is grown or has been grown in the past. In succeeding contributions specific groups of mycotoxins are dealt with in detail. The biosynthesis of lysergic acid and the ergolines in *Claviceps* species is the subject of a contribution by Floss and Anderson. The formation of tricothecenes from mevalonate via farnesyl pyrophosphate in the Fungi Imperfecti is discussed by Tamm and Breitenstein, while Steyn, Vleggaar and Wessels describe the various techniques which have been used to elucidate the pathways of aflatoxin

synthesis from polyketide precursors.

The ergochromes, also of polyketide origin, are dealt with by Franck, while Yamazaki provides us with information concerning a heterogeneous collection of neurotropic mycotoxins, including aspergillid acid, which is formed from leucine and isoleucine, and slaphramine, a lysine derivative.

The biosynthesis of patulin and penicillic acid is considered by Zamir and that of the cytochalasins, a group of mixed biosynthetic origin, by Tamm. Kirby and Robins write of gliotoxin and related compounds, Holzapfel of cyclopiazonic acid, and Sankawa of the anthraquinonoid mycotoxins. The final chapter by Vleggaar and Steyn on "miscellaneous mycotoxins" provides even more evidence of the diversity of the biochemical pathways which lead to these fungal products.

It is a pity that the reader is given so little information about the physiological effects produced by these compounds and the nature of the organisms to which they are toxic. Biosynthesis is, however, the proclaimed subject of the book and the editor and authors have provided us with a veritable mine of information on the subject. This book will prove invaluable to all chemists, biochemists and biologists interested either in secondary metabolism or in the toxins of the fungi. □

Reagan must live with arms control

Arms control has fallen off the agenda in Washington since the accession of Mr Ronald Reagan on 20 January, and nobody is surprised. Mr Reagan himself has a consistent record of indifference on the subject, now strengthened by the Administration's anxiety to be seen to be tough with the Soviet Union. The new Secretaries of State and of Defense, Mr Alexander Haig and Mr Caspar Weinberger, are unlikely to be urging that the Administration should push for further measures of arms control. In this climate, it is therefore a sign of grace — and of European and especially German influence in Washington — that the bilateral talks with the Soviet Union on the problems of limiting "theatre nuclear weapons" are continuing. Yet arms control cannot remain indefinitely in limbo. Sooner rather than later, perhaps in the last quarter of the year, the Administration will be forced to talk to the Soviet Union about something, European interests that there should be substantial progress in this direction are too strong indefinitely to be ignored. Then the non-nuclear signatories of the Non-Proliferation Treaty who went away grumbling from the review conference last September (and whose silence since is mystifying) will become thorns in the flesh of the superpowers again if nothing is done "to undertake effective measures in the direction of nuclear disarmament" as promised by the treaty. Whatever its inclinations, the Administration will find it has no choice but to talk. Where should it begin?

It should start with domestic housekeeping. As things are, the United States is better prepared for building nuclear weapons than for agreeing to dismantle them. To be sure, there is a dedicated government agency called the Arms Control and Disarmament Agency, which in its time has done sterling service and which has also been a means by which distinguished outsiders could make a mark on United States policy. The trouble is that the agency is only one of several sources of analysis and opinion on arms control proposals licensed to speak their minds in Washington. The State Department has often behaved as if the agency sheltering under its wing was a refuge for hopelessly idealistic liberals. But even the State Department cannot expect to have the last word. The Department of Defense and the Chiefs of Staff are separately entitled to speak up, while the White House itself in normal times is well equipped to disagree with everything that everybody else has said. The result is that proposals for arms control treaties usually find their way to the US Senate encumbered by a bewildering variety of conflicting opinions from within the Administration. Since 20 January, however, the Administration has been even less well prepared for action on arms control. The arms control agency has been without a director, and it is not yet clear whether the proposed nomination of Mr Eugene Rostow, a super-hawk, is intended to enable the agency to stand up to Mr Haig or, alternatively, to emasculate it (Mr Rostow once told the Senate Foreign Relations Committee that the only agreement between the United States and the "Russians" of which he thoroughly approved was that for the purchase of Alaska).

Even at this late stage, the Administration would be well advised to rebuild this cumbersome apparatus. The arms control agency owes its existence to the conviction, in the early 1960s, that if arms control were left to the Pentagon and the State Department, nothing would ever be accomplished. It is, however, folly to suppose that the agency could carry through the Senate agreements on arms control to which the Pentagon and the State Department were opposed. Then, with the passage of time, it has

become more and more widely recognized, even by the hawks, that arms control is an integral part of foreign policy and of national security. So much is clear from the working of the healthy clutch of international treaties accumulated since the ban on testing nuclear weapons in the atmosphere signed in 1963. Salt I, which limits the deployment of anti-ballistic missile systems, is more than a mere token of self-restraint by the superpowers. Because of the meetings of the standing consultative commission set up to supervise the working of the treaty, it has become a valuable means of exchanging data and opinions on technical issues. This, for example, is how the function of the Soviet "Backfire" intermediate bomber has been understood in Western Europe and the United States. So, as things have turned out, the process of arms control would be strengthened if the arms control agency were now firmly integrated with the State Department, not left on a limb where it can be disowned whenever the State Department and the Pentagon think it has gone too far. The overriding need is that the Administration should have a mechanism for arriving at one view, not half a dozen, of what it seeks from negotiations.

The Administration must also decide what it is prepared to talk about. The conventional wisdom is that Salt II, the agreement limiting the numbers of Soviet and American strategic weapons that was signed nearly two years ago but never ratified, is now dead. The Soviet occupation of Afghanistan was the occasion (in an election year) for President Carter tactfully not to press the treaty on an unwilling Senate. But nobody is sure of the status of a treaty which is signed but not ratified. In other fields — the Threshold Test-Ban Treaty, for example, which was signed in 1974 but never ratified — both superpowers behave as if the treaty had the force of international law, and complain if they think that one or other of them has violated the agreement. The chances are that both the United States and Soviet governments will find it prudent to behave as if Salt II were a reality. And long before 1985, when the unratified treaty would normally expire, those now saying that Salt II is dead will be crying "Long live Salt III". They will be referring to an amalgam of Salt II and whatever agreement emerges from the talks now under way on the technically daunting problem of limiting nuclear delivery systems of less than strategic range — cruise missiles, Pershing II and, for that matter, the "Backfire" bomber. Salt II is in many ways an unsatisfactory treaty (that could be improved by further negotiation) but the risks of letting it lapse will, long before 1985, seem too great for any administration to contemplate lightly.

The other dead duck from last year's agenda is the negotiation of the Comprehensive Test-Ban Treaty. A year ago, the United States Administration was saying that two months hard talking, and a sufficient measure of political will, would see the treaty signed and sealed. Since the arrival of Mr Reagan and his colleagues, that cheerful talk has quite evaporated. Instead, the military and the weapons laboratories have become eloquent about the risks of dispensing with weapons tests. The problem they identify is real enough, and comes in three parts. First, there are problems of reliability. Nuclear warheads deteriorate in performance with the passage of time, some of them because components such as tritium have relatively short half-lives, some of them because more conventional chemical components go off. The result is that some types of warheads must be refabricated at regular intervals and, in an ideal military world, tested. But there is no reason why the rebuilt bombs should not follow the original designs exactly. Second, there are problems of development. If

somebody designs a new delivery system, should not be weapons laboratories be asked to tailor the ideal warhead to it? The weapons laboratories answer enthusiastically and affirmatively. The truth, however, is that both the superpowers must now have such a range of efficient warheads that the search for perfection cannot substantially affect national security. Third, more important but less tangible, the military (on each side) would be psychologically uneasy (and the weapons laboratories would lose some of their best people) if testing were prevented by means of a comprehensive test-ban treaty. The strength of this objection was consistently underestimated in President Carter's unrealistic times. The result is that too little has been done, in the United States and elsewhere, to prepare the military for living without tests. It would be too much to hope that Mr Weinberger will take on this task so early in his career at the Pentagon. The best hope now is that the pressure of events will persuade him or his colleagues of the importance of the exercise.

For the immediate future, then, the prospect for substantial progress in arms control is far from bright. The new Administration will find itself dragged reluctantly towards Salt III. The Comprehensive Test-Ban Treaty will hang fire until opinion changes towards the second half of Mr Reagan's term. Wrongly, the Reagan Administration will be pilloried when it sets

about the dismantling of President Carter's clumsy anti-proliferation apparatus and may even be persuaded as a result that it had better stay clear of anything to do with arms control. That would be a great misfortune, especially because the agenda the Administration has inherited includes two treaties whose ratification by the United States Senate would bring benefits that are totally unalloyed. The Threshold Test-Ban Treaty (limiting tests to the equivalent of 150,000 tonnes of TNT of explosive power) includes provision for the definition of allowed testing sites, and for the pre-arranged calibration of the seismic characteristics of the underlying rocks, that would immediately improve the efficiency of the seismic detection networks on both sides. The treaty to regulate the use of peaceful nuclear explosions (with which even the Soviet Union now seems disenchanted) provides for similarly open exchanges of technical data about the characteristics of nuclear explosions. Would it not make sense, even for an administration anxious to demonstrate its firmness with the Soviet Union, to ratify (with the assistance of the Senate) these treaties? For as things are, the United States government (like that of the Soviet Union) dares not break the rules agreed, but cannot enjoy the benefits that would accrue from ratifying the treaties. Even Mr Reagan and his colleagues must know that that is absurd.

Can British education be reformed?

The British educational system, long and widely known for its waywardness (the encouragement of school students to abandon those studies of which they are most in need) and excesses (the preoccupation with examinations), may be about to change. The government has now published a document, *The School Curriculum*, that sets out a recipe for a uniform and rational curriculum for British schools and which also promises (some teachers say "threatens") a continuing interest in progress towards its modest goals. Others than the British may not fully appreciate the momentous and historic significance of what the British government has done. Although the education of the young is financed largely from taxation, the central government has no constitutional right to intervene in what is taught in British schools. The only legislative constraint on the school curriculum, embodied in the Education Act of 1944, is that publicly supported schools must provide religious instruction of some kind. For the rest, local educational authorities are constitutionally the final arbiters of the curriculum, but it has never been finally decided whether even they can tell head teachers how the school curriculum should be designed. Indeed, head teachers themselves are frequently at loggerheads with teachers and teachers' unions because their power to decide what should be taught in their schools is circumscribed by teachers' insistence on "academic freedom". Throughout the 1960s, when schools were sufficiently well supplied with funds to be able to experiment with the curriculum, successive central governments justified their cowardly detachment from what has happened by saying that they had no authority to intervene. It is therefore all the more creditable that central government should have chosen to intervene at this point, when there are no substantial funds with which to grease the palms of recalcitrant education authorities.

It remains to be seen how effective the new interventionist regime will be. *The School Curriculum* has only one important argument — that there should be a core curriculum in all publicly supported schools, consisting of language (usually English language), mathematics and science, and that no student in a secondary school should be allowed (let alone encouraged) to give up such a study before the age of 16. In addition, the document says, students in secondary schools "should undertake some study of the humanities designed to yield lasting benefit". The document recites predictable platitudes about the importance of moral education, preparation for adulthood and the like, and is intelligent but also defeatist about foreign language learning. Must not such a moderate and modest programme of reform

surely succeed?

Unfortunately, the outcome is by no means assured. Schools and the teachers' unions have been quick to say that the government cannot will the ends without providing the means — and that there is not merely a shortage of money but of people. For decades, the British educational system has been crippled by the lack of confident teachers of the essential parts of the curriculum as now defined — science, mathematics and modern languages. Even in first language teaching, trendily dubbed "communication skills" by too many schools, the efforts of able teachers are too often offset by those of teachers who believe that any string of words is a measure of a student's creativity, and therefore to be valued. The British government must know that even its modest proposals will not have the influence expected of them unless it can arrange for a general improvement in the quality of teaching. But recruiting more specialists, people with good degrees in mathematics, physics or even French, is no solution. A degree in mathematics is no assurance that a person will be able to explain the working of a slide-rule to a class of 12-year-olds. Nor will similar qualifications in other fields help primary school teachers to persuade even younger children that they are genuinely teachers.

Having embarked on the courageous course of pretending to have an opinion on the school curriculum, the British government has in the process saddled itself with an administrative problem. How will it enable the schools, at least some of which are eager to follow the instructions now implicitly handed down, to do what is asked of them? The most immediate need is not (as the teachers' unions and many schools have been saying) to increase the supply of specialist teachers but to rid the schools system of the tyranny of the public examinations that now dominate the curriculum. Fortunately, having agreed that there should be a reorganization of the public examinations provided for 16-year-olds, the government is well placed to do just this. The ideal would be that it should let schools (or their education authorities) provide school-leavers with suitable certificates and that the public examinations for 18-year-olds, the most distorting of present influences on the school curriculum because of their use as means of selecting students for higher education, should be abolished. Then, paradoxically, the government would find that, having made its point about the pattern of education, it could confidently allow schools to get on with the only task for which they are equipped — teaching young people. Left to themselves, but with clear objectives, they would find the teachers that they need.

European biotechnology lies in disarray

Commission's plan lacks friends

Trouble looms again for the ill-fated European research programme in biomolecular engineering, conceived in 1976 and, after much consultation, proposed to Community states in final form by the European Commission last summer. The Council of Ministers, which has the final authority over such proposals, placed the £16 million (26 million European Units of account (EUA)) five-year programme with its research committee for comment. And the committee now says that it cannot agree on the content, scale or cost of the programme.

The proposal was innovative in its time — it was praised by Jacques Monod and has been broadly backed by European industry, but it now looks unlikely to get approval in any form before November, the next date for a Council of Community Research Ministers. If the research committee had agreed, there was a chance that the programme would have gone through as a "point A" — a proposal that can be approved by any council without debate.

The programme deals with potential scientific bottlenecks in enzyme and recombinant DNA technology — such as provision of cofactors in enzyme-induced synthesis, or problems of expression efficiency in genetically engineered bacteria — through "indirect actions", where the Commission selects and organizes groups around Europe to investigate specific questions and pays half the costs (see *Nature* 283, 125, 1980).

Originally the programme contained six projects, but discussions last year within CREST, a committee of government representatives in which the Commission takes soundings of national views, reduced the number to four, eliminating areas with likely immediate medical or industrial application, and trimmed the budget to 15 million EUA. French representatives requested that half this sum be spent on education and training.

Eventually a "CREST compromise" was worked out, with 4 projects and 15 million EUA of which 20 per cent would be for education. But, at the level of the research committee of council, this compromise has proved unacceptable — as has a further compromise proposed by the secretary of the committee which would reduce the spending still further to 11.8 million EUA. The French members want their 50 per cent education and German members want the number of research projects cut to two, restricting the programme to agricultural applications (basically gene transfer in plants) and

safety questions. Britain appears to back the CREST compromise, or something close to it, all other states would have preferred the original proposal but are prepared to accept that of CREST.

In fact the proposal has fallen foul of the two major obstacles to Brussels-initiated research. First, the concept of a "European" industry benefiting the Community as a whole has not yet taken root, and if a piece of research has a potentially large economic benefit — such as research into cloning vectors, one of the original six proposals — nations are unwilling to share their expertise. The French view of the biomolecular engineering programme exemplifies this attitude: the government wishes the programme to be reduced to a training programme in

recombinant DNA techniques (it has had trouble recruiting for its genetic engineering company, Transgene) and effectively rejects the idea of joint research.

The second objection to Brussels-based work is that if nations already have a research programme in a particular area, they are unlikely to set aside funds in that area for work undertaken outside their control. This is broadly the position of German biotechnologists: they have a large national programme, but research money is tight, and contributing to a Commission-based programme would only distort their priorities.

More Community-minded biotechnologists in both France and Germany, however, point out that long-term progress

German physics in row about Einstein

The German Physical Society (Deutsche Physikalische Gesellschaft) has been shaken by a fierce row over an attack on Einstein published last November in *Physikalische Blätter*, the society's membership journal. Now the editorial board of the society, and the president of the society, Professor Horst Rollnik of the University of Bonn, have dissociated themselves from the original article, by Professor Albrecht Unsöld of the University of Kiel. In a statement in the March issue of *Physikalische Blätter*, they say that Unsöld's article contains statements that are open to misinterpretation, or even false, and promise that the journal will carry an article by an historian of science dealing with Einstein's links with Germany. There is, however, no suggestion that the journal will publish the critical letters it has received in the past few months.

Unsöld, a theoretician now 75, appears to have begun his attack on Einstein at a symposium held at the University of last May, when he said that Einstein (and Haber) was guilty of crimes "no less serious than those of Hitler".

Unsöld says that Einstein's earliest papers were deficient in references to the work of other physicists because of his "narcissism". Unsöld says that Einstein had run out of new ideas by the age of 45, for which reason he turned his attention to public affairs and in particular to "Jewish nationalism", put on a par with the attachment of other physicists (Lenard, Stark and Wien, for example) to German nationalism. The article says that Einstein's move to Berlin in 1914 was motivated by his "enormous salary demands", and that he was frustrated at not being awarded a Nobel Prize sooner because he needed the prize "in order to divorce his first wife".

The article also says that Einstein

travelled outside Germany with increasing frequency after 1920 "to fill the emptiness created by the drying up of his more profound ideas" and to "make propaganda" for the theory of relativity and for the creation of the state of Israel. Unsöld says that Einstein should have foreseen that his letter to President Roosevelt in 1939, confirming the opinion that nuclear weapons could be built, would lead to the destruction of Hiroshima and Nagasaki. He goes on to urge sympathy for those physicists who stayed behind in Germany after the arrival of Hitler, and who were able to resist the penetration of university faculties by "party personalities" while safeguarding the traditions of research and the university libraries.

There has been a torrent of protests against the publication of Unsöld's article, especially from German physicists working abroad. Unsöld has been charged with antisemitism and with mischievous inaccuracy. In reply to one of these complaints, Professor Rollnik explained that he had not seen the article before publication, that its appearance could be accounted for only by a "gross failure" of coordination between the editorial board of the journal (appointed only in 1980) and the editorial staff and that new rules have been devised to prevent the repetition of "such a nasty event".

The disclaimer now published in the March issue of *Physikalische Blätter* says that the journal must be free to publish controversial opinions even when most members of the society disagree, but that Unsöld's article is inaccurate and that its author has only harmed himself in his attempt to defend physicists who worked in Germany during the Third Reich. It remains to be seen whether it will suffice to bring the row to an end.

on applied biology — to which the Brussels programme is directed — depends on the scale and quality of communications among scientists, and that the principal contribution of the biomolecular engineering programme would have been to set up a network of working contacts throughout Europe. A single European state does not have sufficient biotechnologists to make significant advances in competition with the United States or Japan, they argue.

This point appears to have been lost on the research committee of the Council of Ministers, which has now passed the problem to the diplomatic level in Brussels — the committee of permanent representatives, Coreper. But with the present low level of diplomatic concord in the Community, there seems little hope of a resolution.

● Britain's recent white paper on biotechnology was roundly condemned by British researchers at the second European conference on biotechnology at Eastbourne last week. Dr Duncan Davies, whose chief scientist's office at the Department of Industry produced the white paper, made a flying visit to the meeting to defend his position. He was subjected to a barrage of speeches from the floor, but managed to squeeze in that he would review the white paper's provisions on the education and training of biologists. Informed opinion, however, expects little to come of such a review. **Robert Walgate**

European Space Agency Space on the cheap

Paris

The member states of the European Space Agency are still at odds about the future. Although they have agreed to the proposal of Mr Erik Quistgaard, the agency's director-general, that the budget should be reduced to 60 per cent of its present level over the next ten years, they are hopelessly divided on how to spend the money. The problem is that the reduced budget will not support the three programmes that have been put forward — in telecommunications, space transportation systems and science. So the agency is wrestling with priorities.

Quistgaard's suggestion that the mandatory science budget, to which all member states must contribute, should be increased by 60 per cent over the next ten years has so far fallen on stony ground. Britain, Sweden, Spain and Belgium have flatly turned down the proposal, only Germany has agreed to contribute in full.

Lacking unanimous agreement, the agency may therefore have to take the unprecedented step of admitting optional contributions to scientific programmes. That, according to Ernst Trendelenberg, director of scientific programmes, could divide European space scientists into privileged and under-privileged depending on their nationality.

Germany and France are the most likely to favour this approach, but for different reasons. Germany would like to divert some of the money spent on Spacelab to science, and France is keen that there should be a steady stream of satellites for launching with Ariane, whose development it has supported heavily. Britain, on the other hand, says the agency is too inefficient to justify more spending on science.

The most heated debate in the agency, however, is about the choice of space applications for the next ten years. The two chief candidates — space transportation systems and telecommunications — have been proposed by France and Britain. France argues that Europe must have a launcher to rival the space shuttle, especially if materials processing experiments on Spacelab demonstrate that space has commercial potential. It would like to develop more sophisticated versions of Ariane and ultimately an unmanned partly-reusable space transportation system called Solaris, which is expected to be put before the agency's council at the end of the year.

France disagrees with Britain's proposal to spend more on telecommunications on the grounds that that should be left to industry. Both France and Germany withdrew from early plans to build a large satellite for direct broadcasting, preferring instead a bilateral programme. Neither believes that the "Large Satellite Programme" (L-sat), due to be approved

Quistgaard awaits orders

Paris

Erik Quistgaard, director-general of the European Space Agency, is optimistic. The present stalemate between the member states, he says, might be broken if the users of space technology were more intimately involved. Thus post offices, users of remote sensing data and industrial users of experiments on Spacelab rather than government departments should have more influence over what the agency does. The problem is that although most states know what they want from space, few are decided about their expectations of the agency.

Mr Quistgaard believes that it is up to member states to tell him what they want. Some delegates, however, are looking to him for solutions. The rejection of his proposal that the science budget should be increased is hardly encouraging.

Quistgaard believes that Europe can and should compete with the United States and others in telecommunications, remote sensing and space transportation systems. He favours unmanned space transportation systems as an alternative to the space shuttle. **Judy Redfearn**

in June by Britain, Italy and some of the smaller countries, goes sufficiently beyond their own plans to justify participation. Britain, on the other hand, with a smaller space budget than either France or Germany, sees L-sat as its opportunity to compete for world markets.

The hope is that these two conflicting views can be reconciled. Professor Hubert Curien, director of the Centre National d'Etudes Spatiales, believes that Britain may be moving towards the view that space transportation systems must be developed within the agency. And John Hawkes, of the British Department of Industry, thinks that his French colleagues may now be more ready to agree that telecommunications development beyond L-sat should be supported on a European scale.

If Mr Quistgaard is to put his ten-year plan into operation, he needs to know soon which of these options the agency should be studying. To pursue both would entail scrapping the agreement reached on the future budget. **Judy Redfearn**

Taking note, or shelving?

The British House of Commons last week "took note" of the European proposed programme on biomolecular engineering, a mechanism which allowed the Under Secretary of State for Industry, Mr Michael Marshall, to state the government position on the latest version of the programme.

The original proposal (for 26 million European Units of Account (EUA) over five years) was "over-ambitious in both scope and expenditure", said Mr Marshall, but the shift of emphasis away from research and towards training in the revised proposals (an 11.8 million EUA four-year compromise proposed in Brussels) "is of an extent not hitherto contemplated".

Without naming France, Mr Marshall indicated that the government did not share the French view that there is a significant lack of training opportunities. Nevertheless Britain would continue to work towards an acceptable compromise, he said.

Tam Dalyell MP, described by one member of the House as "almost a walking Select Committee on Science and Technology", warned the minister to be wary of the French position, saying that the new proposals "by pooling training, hand over British expertise to the French for little or no return". The House took note. **Robert Walgate**

Cystic fibrosis

Diagnostic hopes

Techniques now being developed at various centres in Britain and the United States have stimulated optimism about new approaches to the prevention of cystic fibrosis. Workers in the field are particularly excited by the prospect of being able to detect carriers of the genetic defect.

Among genetic deficiency diseases, cystic fibrosis is peculiar in that the nature of the underlying molecular defect is as yet unknown. The belief that only a single gene

is involved has, however, recently been confirmed by Romeo (Bologna), working with records of dispensations for cousin-cousin marriages accumulated at the Vatican. Among Caucasian populations, the frequency of carriers of defective genes is thought to be 1 in 20. The Vatican records have confirmed that cystic fibrosis is an autosomal recessive disease, accounting for the normal incidence in Northern Europe of 1 in 1,600.

Attempts at antenatal diagnosis of cystic fibrosis have been based on the virtual absence, in those with the overt disease, of an uncharacterized proteolytic enzyme. This technique, originally developed by Dr Henry Nadler in Chicago, is now being taken up at other centres. It may eventually be possible to offer amniocentesis to pregnant women who have already produced one child with cystic fibrosis, although the frequency of false positives and false negatives has not yet been determined confidently.

Two techniques for the recognition of carriers are being developed, one of which is based on the occurrence in the serum of both homozygotes and carriers of a protein apparently characteristic of cystic fibrosis. Last year, Dr David Brock's group at the Department of Human Genetics at the University of Edinburgh reported the raising of antibodies against the protein (Manson, Jean and Brock, David J H, *The Lancet*, 16 February 1980) and the possibility that these might be used to distinguish between cystic fibrosis patients (carrying a full dose of the protein), carriers (with a smaller amount) and normal people. Since then, better techniques for raising antibodies have been developed, and there are plans for the development of monoclonal antibodies. The second technique, developed in Los Angeles, is based on the differential response of cystic fibrosis patients, carriers and normal people to the administration of the drug ouabain.

The hope now is that a relatively straightforward way of recognizing carriers may reduce to manageable proportions the provision of amniocentesis for mothers at risk of producing children with cystic fibrosis. In Britain, the Department of Health is under some pressure to prepare for a pilot scheme against the time when the diagnostic techniques are fully developed.

Genetic screening may well be possible before the nature of the underlying defect is understood. One possibility is that the protein characteristic of cystic fibrosis is in normal people removed by the proteolytic enzyme which is the basis of proposed diagnosis of the disease by amniocentesis. In Britain, Professor R. Williamson (St Mary's Hospital Medical School) has embarked on a programme for the identification of the cystic fibrosis gene using techniques of chromosome sorting and genetic manipulation.

Financial support for most of the British research in this field is provided by the

Cystic Fibrosis Research Trust, which is now spending more than £500,000 a year. It is a sore point with those involved that the Medical Research Council's contribution to work in the field, although small, was exaggerated in a reply to a parliamentary question last October.

Safety at Windscale

Yes we were wrong

The British nuclear industry's site at Windscale, the source of a long sequence of mishaps in the past decade, was last week given an adverse report by the Health and Safety Executive, the organization in charge of the Nuclear Installations Inspectorate. And British Nuclear Fuels Limited, the owner and operator of the site at Windscale, put its hand on its heart and acknowledged that it had been at fault.

The report by the Health and Safety Executive is largely concerned with managerial failures at Windscale. It says that British Nuclear Fuels had allowed the condition of the several plants at Windscale to deteriorate until by the early 1970s, their safety could not be assured, and that the efforts made since 1974 to enhance the safety of the Windscale facilities further complicated the assurance of safety by their demand on resources. The report complains that the company paid too little attention to the filling of senior posts at Windscale and that the arrangement whereby the Northwest Area General Manager is responsible for safety in the whole of Windscale but also at other plants means that his responsibilities are too much diluted.

The report says that most incidents at Windscale have arisen because of mistakes in the execution of routine tasks. About a quarter of the 30 or so incidents reported each year since 1976 have involved the exposure of people to doses of radiation exceeding the limits laid down. The inspectors say that the managers of the plant must provide workers on the site with regularly updated and more explicit instructions for carrying out routine tasks and that a promised review of safety procedures should be completed more quickly than now seems likely. In the long run, the Nuclear Installations Inspectorate wants to see a system for the independent audit of safety at Windscale.

The effect of the Health and Safety Executive's report on the publicly owned parts of the British nuclear enterprise is likely to be far-reaching. British nuclear engineers appear to acknowledge that Windscale, because of the way in which it has been created by the addition of new plants to an already overcrowded site, and because of its relative antiquity, is not the ideal model for the safe operation of nuclear plants. But other nuclear sites are likely to encounter similar problems which will be less readily excused.

US university regulations

Complaints listed

Washington

Jumping on the anti-regulation bandwagon which helped propel Mr Ronald Reagan into the White House last November, US colleges and universities are eagerly compiling a list of federal regulations which they feel are stifling the productivity of their educational and research efforts.

One regulation that the universities have in mind is the notorious Circular A-21, issued by the Office of Management and Budget, laying down strict accounting rules which must be obeyed by any scientist and his or her institution receiving federal research support. "A-21 is at the top of our priority list for reform", Mr Sheldon Steinbach, general counsel of the American Council on Education, said last week.

Another rule which the universities would like to see changed is the requirement that scientists should provide a precise account of the way that their time is divided, not only between teaching and research, but also between different research projects. Another relates to cost-sharing between universities. And although the Carter Administration, in its last month in office, took steps through the Office of Management and Budget and the Office of Science and Technology Policy to reduce the impact of the A-21 rules, many universities feel that they are still far from satisfactory.

The universities' point of view had already been presented to Vice-President George Bush, who has been appointed by President Reagan to head a task force on regulatory reform, and has announced the Administration's intention to defer several new regulations proposed by Mr Carter, and also to take a close look at several existing rules to see if they should be revised.

Last week, Mr Bush was presented with a nine-point plan to streamline federal rule-making which had been drafted by 62 leading businessmen and educators organized by the American Council on Education into a Business Higher Education Forum. The forum's statement linked together the complaints made by the business community about, for example, the impact of health and safety regulations, and those coming from the academic community about the general burdens of educational regulation.

The report of the forum says that, as a result of the many educational reforms introduced over the past twenty years, from rules about facilities for handicapped students to affirmative action programmes, regulation of higher education "has mushroomed", with 400 laws on the statute book overseen by 34 committees of Congress.

One complaint is the economic impact of the regulations. According to Howard Bowen, an economics professor at the

Claremont Graduate School, federal regulations alone inflate costs on 3,200 US campuses by an estimated \$3,000 million a year. And the Business Higher Education Forum quotes the widely used — although often challenged — calculation by economist Murray Weidenbaum, now chairman of the Council of Economic Advisors, that federal regulations may be costing US industry \$100,000 million a year overall.

But there are other factors at work as well. "The most important of the regulations' effects is the growing and unwelcome degree to which government intrudes into the private sector, compromising the capacity for independent action in business, labour, academic institutions and elsewhere", says the forum report.

The Bush task force has already said it plans to review two existing regulations covering research. One requires college professors and researchers receiving federal grants or contracts to obtain government approval for leave of absence, changes in research methods or transfer of the research to others, the other requires colleges and universities to share certain percentages of the cost of research financed by the federal government.

Research administrators are cautiously optimistic that, given the general anti-regulatory stance of the new Administration, they will achieve significant changes, a step towards what the American Council on Education forum describes as "a more systematic, rational national policy on regulation".

David Dickson

French nuclear power

Close to the brink?

Brussels

The breakdown in the electricity supply from the French national grid to the nuclear reprocessing plant at Cap de la Hague, at the tip of the Cherbourg peninsula, which occurred in April last year (see *Nature* 24 April 1980, p 653), came within an ace of becoming a major catastrophe. That, at any rate, is what the Brussels-based international socialist group Agenor is claiming.

Agenor has published an account of the incident based on the research of two groups of critical scientists, GSIEN in France, and PERG (Political Ecology Research Group) based in Oxford. The report claims that when the electricity supply was restored the emergency generator "blew", putting all the plant's electrically operated mechanisms out of action. By pure chance one of the worst consequences was avoided. Ten minutes earlier a 30-kg load of plutonium was being prepared. Without the electricity, the agitation needed to prevent the plutonium going critical would have stopped.

The power failure also stopped the cooling of the reservoirs containing radioactive waste from all of France's reactors.

Nuclear Structure Facility

More delays ahead

Britain's Nuclear Structure Facility, under construction at the Science Research Council's Daresbury Laboratory in Cheshire, has run into new problems. The 30-MV tandem Van de Graaf accelerator had been expected to produce its first beam for experiments this month, but the latest setback means that full operation is unlikely before the autumn. The problem is dust, which caused a short circuit across the laddertron — the aluminium and plastic belt which carries charge up the 40-m column to terminals — during a recent trial. The resulting break in a couple of plastic links in the laddertron has been relatively simple to repair, but getting rid of the dust is proving more difficult.

The Nuclear Structure Facility, which should provide a variety of ion beams for nuclear structure studies, has had a long, and not always easy, history. The Science Research Council bit off rather more than it could chew when it decided in 1972 to build a tandem Van de Graaf accelerator that exceeded the capabilities of machines operating at the time. The highest voltage achieved by standard machines was then about 15 MV. Design and technical problems have considerably increased the

Within 10 hours the waste would have begun to boil, releasing caesium-137 and rubidium-106 and making it difficult to gain access to the plant to restore the current and restart the cooling. If that had happened, within three days a radioactive cloud would have formed, and the prevailing southwesterly winds might have carried the cloud as far as London. The uncooled and dry waste left in the reservoir would then have melted down, reaching the water table and causing a steam explosion. At the Cap de la Hague site not only radioactive waste but also stored plutonium would have been distributed over a large area.

On 6 January this year a different accident occurred, the news of which the authorities had more difficulty in suppressing. A fire broke out in a trench used for dumping cladding removed from around the used fuel rods of graphite gas reactors. When alarm bells rang in several workshops on the site, the reaction was to disconnect them. Only later was it realized that radioactivity was coming into the workshops from outside. The fire burned for 15 hours. According to measurements taken by the unions, the level of beta radiation on the site had risen to 26 times the permitted level and alpha radiation to 6 times the permitted level. According to Agenor, the French Atomic Energy Authority (COGEMA) avoided informing the workers downwind of the fire and denied there was any danger to the local population. The radical trade union CFDT had produced figures to show that milk has been contaminated throughout the

building time and the cost.

The dust problem first became apparent last November. There are two sources of dust — beds of alumina pellets used to dry out sulphur hexafluoride gas which surrounds the tandem, and the bearings used in the construction of the machine. A short test last summer revealed no dust problem. For that test, the machine was run without drying the sulphur hexafluoride insulating gas and, according to Dr R Voss at Daresbury, not for long enough for the dust from the bearings to become a problem.

Work is now concentrated on removing all dust from the machine. Dust from the alumina beds should be minimized by passing the gas through more slowly, but it may be more difficult to eliminate dust from the bearings. However, after a few hundred hours of operation, bearing dust should fall off dramatically. After that, the plan is to catch residual dust in traps built into each rung of the laddertron.

The result is that the facility will be late coming on line. It is now hoped that the high-voltage performance can be demonstrated within one or two months, the accelerator tube within the following two months and that commissioning will be complete two months after that. The first experiments are likely in September or October.

Judy Redfearn

Cherbourg peninsula

The intention of GSIEN, PERG and Agenor is to discredit the technology of the Cap de la Hague reprocessing plant and to go on to show that the nuclear power strategy of France as well as Western Europe is wrong.

As well as having problems with safety, the Cap de la Hague plant is not fulfilling its tasks. Cap de la Hague started processing oxide fuel in September 1976, a year behind schedule. The planned capacity is 800 tonnes a year but by 1980 the total amount processed was only 340 tonnes. In the meantime, France has gone on negotiating contracts to reprocess the waste from Japan, Germany, Belgium, Spain, Sweden, the Netherlands and elsewhere. To manage what is estimated to be a commitment to reprocess 6,000 tonnes, France is building two more plants, each with an annual capacity of 800 tonnes. Neither is likely to be in operation by 1988, and meanwhile the waste is being stored.

As well as being behind in coping with nuclear waste, Cap de la Hague is not producing enough fuel. In 1980 the plant handled enough uranium oxide to produce only one tonne of plutonium. Agenor argues that at this speed the fast-breeder strategy falls flat on its face. The initial fuel load of plutonium needed at Malville, a 1,300-MW reactor, is 4.5 tonnes, so that the idea that France or Europe can become self-sufficient with fast-breeders is implausible. Europe boasts only one other reprocessing plant, that at Windscale in the United Kingdom.

Jasper Becker

CORRESPONDENCE

Genetic weaponry?

SIR — The problems of implementing the Helsinki accords in Soviet Russia have been raised once more in your issue of 15 February (p 437) where the case of David Goldfarb was mentioned. I have known David Goldfarb for many years. He was head of the Laboratory of Molecular Genetics of Bacteria and Bacteriophage of the Soviet Academy of Sciences. He has asked to emigrate to Israel and a visa was denied on the grounds that "he had access to classified work".

David Goldfarb was never involved in classified work and did not even have security clearance — as so many scientists in Soviet Russia have. He worked on the genetics of bacteria and bacteriophage. If such research is classified, it means that Soviet Russia intends to use molecular genetics for biological warfare.

So far as is known, the USSR Academy of Sciences is consulted when a scientist asks for an emigration visa. One wonders if the Academy will officially and openly subscribe to the decision of the Soviet authorities according to which molecular genetics is a potential weapon and a military secret.

ANDRÉ LWOFF

Institut Pasteur, Paris, France

NRPB and risk

SIR — It must be admitted that one does not know what happens within an organization without being a part of it. It is equally true that being a part does not automatically make one a reliable critic of it. We have these assertions in mind upon reading Mr S. G. Goss's letter on risks at the National Radiological Protection Board (*Nature* 289, 316, 1980).

We have the highest respect for the scientific integrity of Sir Edward Pochin and the late Dr G. W. Dolphin, and their thoughtful attempts to publish reliable information on radiation risks.

We further believe that this view is shared by other US colleagues who have had the opportunity of interacting with these two. Derogatory evidence would have to have a decidedly firmer foundation than that offered in the Goss letter to change this viewpoint.

WILLIAM J. BAIR
ROY C. THOMPSON
HERBERT M. PARKER

Battelle Pacific Northwest Laboratories,
Richland, Washington, USA

Conservation sites

SIR — In his letter of 12 March 1981, Dr C. Muir criticises actions and advice of the Nature Conservancy Council (NCC) over Sites of Special Scientific Interest (SSSI) on the grounds that such sites are misguidedly chosen to protect endangered species, because species extinction is a natural and inevitable process, and that the site notification procedure imposes an unacceptable financial burden on landowners. The NCC does not notify SSSIs from "caprice" but because Parliament in its wisdom conferred this duty upon us, as a key part of a national strategy for nature conservation. We continue to do this because a very large number of concerned people believe that SSSIs are important to the conservation of wildlife and physical features.

Most extinctions during the last 2,000 years have been man-induced, and it is this accelerated loss that we are trying to stem. By

2000 AD the world will have lost no fewer than one million of the plant and animal species existing today, mainly through habitat destruction and over-exploitation. In Britain many indigenous species could become extinct. Whether this is held to be evolution or not is irrelevant: the fact is that many people do not wish such losses to occur and look to NCC and other bodies to prevent them.

SSSIs are in any case not chosen just for the presence of rare or endangered species, but to give a national network of important semi-natural habitats. Many are selected quite separately for the importance of their geological and physiographic features. The term "scientific interest" is interpreted broadly as the value of the biological and physical attributes of a site to that informed sector of society which has a concern for such phenomena. The NCC has defined criteria for evaluation of these attributes based on the full range of public interest involved, which is clearly wider than scientists alone.

The SSSI device is one of the few means available for defending the important areas for nature conservation but its actual inadequacy in this respect is currently the subject of lengthy parliamentary debate on the Wildlife and Countryside Bill. Our concern is indeed to safeguard these sites in perpetuity. It is a staggeringly narrow and mechanistic view which holds that once "objects or phenomena" have been "studied" they are of no further value to science and can, by implication, be allowed to disappear. And beyond this, who has the confidence to assert that all possible knowledge has been gleaned from any object or phenomenon?

The responsibility of government to cater for nature conservation as a public interest is not, in a democratic society, altered by the fact that some people find the resulting measures inconvenient to their material interests or irrelevant to their personal beliefs. And just to get things in proportion, the sense of official priority accorded to nature conservation in public affairs is reflected in the £10 million annual budget of NCC, compared with £700 million allocated to agricultural support and £9,500 million to defence.

The NCC has long accepted that when owners and occupiers of land are asked to incur a material loss in order to sustain a nature conservation interest, the principle of compensatory payment is entirely fair. This principle would remain an integral part of the additional site safeguard measures which NCC has been seeking in the Wildlife and Countryside Bill. It seems equally reasonable to ask that owners and occupiers of land accept that they have, on behalf of the nation, a responsibility in stewardship for the national heritage of nature which is now suffering such severe and accelerating losses. We are all increasingly enmeshed in a single society, and when the owners and managers of our national resources ask the taxpayer to help their private circumstances by direct or indirect cash hand-outs, another point of principle arises. This is that these parties should also accept that such funds are distributed across the whole wide spectrum of taxpayer interests, according to a balance of adjudication through the proper agencies of government, of which NCC is one.

Selling Darwin

SIR — So much has been written on Darwin and Marx, since Halstead's original diatribe against the use of cladistics in the displays of the Natural History Museum (*Nature* 288, 208, 1980), that I wonder whether these two venerable gentlemen are not now reaching for their pens to set the record straight. Until *Nature's* Olympian warnings (26 February, p 735) on the "selling out on Darwinism" in the museum (and by association other new evolutionary approaches) one felt safe from the bogies in Halstead's head. Now that they are out and about rather than dead and buried, it is amusing to consider the original error which gave rise to them.

Halstead's polemics "follow like a tedious argument of insidious intent" (T. S. Eliot). His accusation that cladists and proponents of "punctuated equilibria" are furthering the Marxist concept of dialectical materialism reveals his ignorance of the fundamentals of this concept and of Darwinism. If it is necessary to find a biological phenomenon in keeping with dialectical materialism, then Darwin and not "punctuated equilibria" provides a perfect example. According to dialectical materialism (unsullied version) there are two inter-related components to every process in that a gradual accumulation of small quantitative changes leads inevitably to a qualitative change of state. Engel's favourite scientific example was the boiling of water. A qualitative change from liquid to gas only occurs after a sufficient quantitative increase in the thermal agitation of the molecules has taken place. According to popular Darwinism a gradual quantitative accumulation of allelic differences as an adaptive response to a specific environment leads inevitably to a qualitative change of state (the inception of reproductive isolation/speciation). If dialectical materialism upsets Halstead he would do better to dismantle 130 years of Darwinism.

Ironically the precise mechanism by which natural selection could increase reproductive isolation perplexed Darwin and, despite the subsequent attempts of Fisher, Muller and Dobzhansky to explain how this might happen, we have little empirical data. "Let me first say that no man could have more earnestly wished for the success of Natural Selection in regard to sterility than I did, I always felt sure it would be worked out but always failed in detail" (Darwin letters to Wallace and Huxley). Notwithstanding these doubts and lack of data Darwinism flourishes today as an explanatory mechanism of adaptation that leads to speciation.

The theory of "punctuated equilibria" does not see species formation necessarily as the inevitable consequence of microevolutionary adaptive differences. It dissociates (to an extent) quantitative (microevolutionary) from qualitative (macroevolutionary) phenomena. Thus with regard to the process of adaptation, it is Darwinian. With regard to the process of speciation, there are several current notions (ranging from possible developmental constraints on phylogenetic progress to possible biological effects of saltatory and rapidly spreading changes in genome organization) that, although novel to a degree, leave no room for instant creationism or the demise of Darwin, in the way it is construed.

They are basically concerned with differential rates of evolutionary change, and the precise role of selection has not, as yet been ascertained. We should not be too surprised if speciation turns out to have an accidental as well as an adaptive component. The imaginative and enquiring spirit of Darwin lives in all except the minds of those with other axes to grind.

I have a feeling that Darwin would be overjoyed at the general acceptability of his concept of fine-grained adaptation under natural selection, and would not be unreceptive to its possible dissociation as a process from that of speciation. Marx, on the other hand, could but grunt that a dissociation of the two processes no longer requires the inevitability of a change of state of one species into another.

From the museum...

SIR — As music is the food of love so surely debate is the nourishment of science, but the crashing cymbals of your leading article of 26 February were a discordant accompaniment to a meagre meal¹. Your subsequent article² sets the stage for a more reasoned discussion.

Controversy and debate over the hypotheses associated with the concept of organic evolution have recently received considerable attention. It can hardly be described as a rot permeating just the British Museum (Natural History) but rather the open questioning of evolutionary theory by serious biologists and philosophers — a fact apparently denied in your first leading article. Furthermore there are clear indications of unease amongst educationalists^{3,4} at the way in which the concept of evolution is being taught, not as a hypothesis open to criticism but as a fact.

Many practising biologists and teachers echo Olson's remark "Evolutionary theory should be treated like any other scientific theory, as a matter for dispassionate and objective study of the evidence available"⁵. Yet this only reflects the more pungent and provocative comment made by Darwin's "bulldog" over a century ago "the scientific spirit is of more value than its products, and irrationally held truths may be more harmful than reasoned errors. Now the essence of the scientific spirit is criticism"⁶.

The views of many scientists in this museum are encapsulated in a quotation from the museum's "recent brochure"

Biologists try to reconstruct the course of evolution from the characteristics of living animals and plants and from fossils, which give a time-scale to the story. If the theory of evolution is true, the features used to classify species in groups were acquired by the common ancestor of the group and inherited by the living descendants. In this light, the groups-within-groups of classification are seen as the descendants of more or less remote common ancestors. And classifying animals and plants is a way of expressing ideas about the course of evolution. This is why classification is interesting and important to biologists, and why the work of classifying is never finished. For new discoveries lead to new ideas about the course of evolution.

Our understanding of the theory of evolution is that it is an amalgam of many subsidiary hypotheses, related not only to the patterns of

organic diversity but also to the mechanisms whereby they arise. Here we are faced with a core theory and its protective satellite belts. Clearly various aspects of these hypotheses have been criticized and improved upon, and there is no reason to believe that this evolution has stopped, nor should we pretend that it has stopped. As practising systematists we recognize and we do not underestimate the enormous heuristic value of the theory as a stimulus to research.

The theory of evolution must surely be considered an "open question" and we therefore agree that "in the public presentation of science, it is proper whenever appropriate to say that disputed matters are in doubt"⁷. We cannot see, however, how the views expressed in the museum's brochure indicate any divergence from such an objective. Rather, they make a positive statement about the utility of the theory as an explanation for the diversity of life.

SIR — Dr Colin Patterson¹ says that cladistics is "not about evolution". Cladistics may therefore be considered essentially a method of classification. Based on morphological characters it arranges taxa into a hierarchy and the hierarchy itself has no necessary phylogenetic implications². Since cladistic classifications are based on "derived" similarity, it seems to have been accepted³ that they may resolve the classification hierarchy more fully than traditional classifications, which are based on "clustering" similarity⁴.

If this is all there is to cladistics then at least its taxonomic substance seems uncontroversial. However, any such hierarchical classification, whilst practically useful, is essentially non-scientific⁵ as the aim of science is to explain simple taxonomic relations, then to test the explanation (scientific theories) to see if they make sense⁶. Evolutionary theory is one such scientific theory⁷.

Cladistic method can be incorporated into evolutionary theory by simply accepting that the cladistic hierarchy represents an assumed time axis, a view taken by Hennigian cladists. A historical sequence is "predicted" from the morphology of organisms and in context of Popperian concepts of science, cladists have gone on to compare the congruence of such predicted sequences with other such sequences based on different, semi-independent lines of evidence, such as historical geography⁸.

However, stratigraphy can also be used constructively in such comparisons to call into question the sequence of taxa presented by cladograms and thus to test the usefulness of the hypothesis outlined above⁹.

Cladists to date have applied the concept of testing mainly from an internal perspective of character analysis¹⁰, and historical time-space coordinates of taxa have in general been ignored. The cladogram has thus been regarded as absolute, whilst evidence from stratigraphy, because it is incomplete, has been recognized as relative — and apparently therefore as worthless¹¹. Little attempt has

been made to hold the cladistic system itself up to test. It seems to have been overlooked that cladistic classification may make morphological evidence seem convincingly complete, even though it is not actually complete. I do not understand how a system that is relative (cladogram) can be assumed to be absolute and thus used universally to ignore or "refute" historical evidence that is actually true¹³. The view promulgated here regards both sets of evidence as relative, and thus as commensurable. Cladograms present a relative sequence and stratigraphy presents a relative sequence, and both have their own semi-independent corroborators and falsifiers. In actual practice the testing role of stratigraphy would therefore be difficult, a sign of a mature science^{9,12}, in some cases the stratigraphy may be trusted more than the cladogram, in others the cladogram may be relatively well corroborated¹³.

It is, on the other hand, naively easy to question the cladistic system as a basis for delimiting species. Since cladistic hierarchies reflect characters of organisms, and since such characters are expressed as a hierarchy of proper sub-classes (monothetic sets)⁴, a logical consequence is that classes cannot be discriminated from individuals within the context of character analysis. Men and women form cladistically distinct taxa, and pregnant women a taxon nested within women as a whole. Straightforward genealogical observation refutes this, since a pregnant lady can deliver a son and return to her generalized condition. This argument may seem facile but for the fact that one cladist has recently described several new species out of what many evolutionists might take to be sub-specific populations¹⁴. At any rate there is a potential danger of over-splitting taxa.

My view differs from some of my colleagues in that I maintain cladistics is about evolution and that any sensibly testable system will recognize that evolution is a complex, mature theory, requiring complex modes of testing beyond "naïve falsificationism". Basically I consider evolution and the fossil record as very much the proper context for cladistics and not the converse. It is surely commonsense to use historical evidence to examine history and not to view it askance through a haze of global aristotelian philosophy of character analysis, as transformed cladists appear now to be doing. Transformed cladists may justly have rediscovered Aristotle, but if they decide to wipe out Galileo they reject not only Darwin but all of modern science¹².

NEWS AND VIEWS

Tissue-specific expression of α -amylase

from R A Flavell

TISSUE-SPECIFIC expression of eukaryotic genes is always intriguing but of particular interest are cases where the expression of a given type of protein is confined to a few tissues, yet where the level of expression in each of these tissues differs. The α -amylase genes belong to such a system. α -Amylase is produced at high levels in salivary glands and the pancreas, but at much lower levels in the liver. Previous studies on the α -amylases of the laboratory mouse have suggested two structural genes, designated *Amy 1* and *Amy 2*. Several recent papers from a group at the Swiss Institute for Experimental Cancer Research describe the molecular organization of these genes. A single gene, *Amy 1A*, encodes both the liver and salivary gland amylases (which are identical proteins). Differential expression of these two mRNAs probably requires the use of at least two different promoters for a single cellular gene. Equally interesting, differential splicing is required for the generation of these two overlapping, but non-identical mRNAs. The second gene (*Amy 2*) encodes pancreatic α -amylase, which has a different primary sequence from the salivary gland/liver forms (Schibler *et al* *J molec Biol* **142**, 93, 1980; Hagenbuchle *et al* *Cell* **21**, 179, 1980).

The notion that differential splicing can be used to regulate gene expression is not new. Indeed, this principle was borne out by the detailed study of viral transcripts where, in several cases, overlapping genes have been found. A well known example is that of the gene products of the early region of simian virus 40, the tumour antigens T and t. t is encoded in a DNA segment colinear with the T gene. Although t mRNA is spliced, this splice occurs after the stop codon and does not, therefore, affect the t antigen protein-coding regions. T antigen is produced from essentially the same mRNA by splicing the region encoding the N-terminal segment of t antigen to the same splice-acceptor sequence as is used in t mRNA. The result is the elimination of the t-antigen stop codon and the fusion, in a compatible reading frame, of two protein-coding segments,

translation of this RNA generates the mosaic T antigen. This is a simple example. The characterization of adenovirus RNAs by a large number of groups has revealed a dazzling spectrum of gene products generated by both differential use of promoters and differential splicing (see review by Ziff *Nature* **287**, 491, 1980).

Viruses pay a premium to keep their genomes small, and overlapping genes are an excellent way to compress a lot of information into a little space (as in the smaller bacteriophages such as ϕ X174). There is little indication that higher organisms have gone to much trouble to trim down the size of their genomes. The average *Nature* reader has 3×10^9 base pairs of DNA per genome, give or take the odd supernumary chromosome, while salamanders, whose aspirations are significantly more modest, possess up to 10^{10} base pairs of DNA per haploid genome. Since it is believed that only about one-tenth of our DNA is used to encode proteins, one might predict that overlapping genes would be restricted to the viruses and that the host genomes would use the more familiar path of gene duplication to generate the same type of diversity. Not so, says α -amylase.

The story runs approximately as follows, with certain details omitted for simplicity.

The primary structures of murine liver and salivary gland α -amylase mRNAs have been compared by sequence and S_1 nuclease/hybridization analyses, and this has been described in a recent issue of *Nature* (Hagenbuchle *et al* *Nature* **289**, 643, 1981). These mRNAs are essentially identical except for the 5'-untranslated region, which is 206 nucleotides long in the case of the major liver species, but only 95 nucleotides in the salivary gland mRNA. Comparison of these sequences shows that both liver and salivary gland mRNAs share the 48 nucleotides of the 5'-untranslated region immediately adjacent to the coding region.

The secret of how this mosaic structure is

generated was revealed by a structural analysis of the chromosomal α -amylase genes. Young, Hagenbuchle and Schibler (*Cell* **23**, 451, 1981) cloned the α -amylase genes, located the mRNA-coding segments of their clones and determined the DNA sequence of the 5' areas of the gene, the region described in the current study covers approximately the 5' one-fifth of the mRNA-coding region. It turns out that the liver and salivary gland α -amylases are encoded by the same mosaic gene. Four exons have been found so far (there are presumably several other exons in the 3' regions of the gene, but these have not been analysed in mouse, for the rat, see MacDonald *et al* *Nature* **287**, 117, 1980) which correspond, respectively from 3' to 5', to an internal coding region (called exon 4 here), the 5'-terminal coding region plus the 45 nucleotides of the 5'-untranslated region (exon 3), common to both mRNAs, and two alternative 5'-terminal exons — one of 161 nucleotides (exon 2), which is utilized in liver α -amylase mRNA, and one, about 2.8 kilobases further to the 5' side in chromosomal DNA, of 50 nucleotides (exon 1) which is used for the salivary gland mRNA. The two alternative mRNAs are probably obtained by differential transcription and/or processing but these points remain to be elucidated. There are promoter-like TATAA boxes at the usual 24 (± 1) nucleotides upstream from both exons 1 and 2 — it is plausible⁵ (see Young *et al op cit*), therefore, that transcription initiates at exon 1 in the salivary gland and exon 2 in the liver. Equally, transcription could initiate at both sites and only the mRNA containing the appropriate leader might be exported to the cytoplasm in the relevant tissue. Whatever the mechanism, the uncapped liver-type leader sequence (exon 2) must presumably act as an intron in the salivary gland transcript, differential splicing must ultimately generate tissue-specific mRNAs with exons 1, 3 and 4 being spliced in the salivary gland and 2, 3 and 4 being spliced in the liver. As Young and his colleagues point out, this type of situation also exists in the immunoglobulin genes where multiple J regions exist in the active,

R A Flavell is at the National Institute for Medical Research, London

rearranged, K-chain gene, for example, only one of these is destined to appear in the mRNA, the remainder being removed by differential splicing

Why does the mouse go to all this trouble? Any explanation should consider the fact that α -amylase mRNA accounts for 2 per cent of the cytoplasmic mRNA in the salivary gland, but only 0.02 per cent in liver. This level may reflect the transcription rate from the two genes, the 'salivary gland' promoter would then be considerably stronger than the 'liver' promoter. Alternatively, the rate of RNA processing and/or export to the cytoplasm may be different for the two mRNAs. Another clue may reside in the fact that the liver mRNA has a much longer 5'-untranslated

region than the salivary gland mRNA. It is possible that this affects the translation efficiencies of the mRNA (see 'Discussion' in Young *et al.*). Although the explanation for this fascinating genetic mechanism is the subject of future work, it is, of course, likely to be tied up with the primary question — what determines the different level of α -amylase in two different tissues?

In the rat (and other mammals) the situation may be even more complicated. MacDonald and his co-workers (*Nature* 287, 17, 1980) have analysed the rat α -amylase genes and these studies point to at least five non-allelic α -amylase genes or pseudogenes. The further elucidation of the expression of the α -amylase gene family remains a mouth-watering prospect. □

Antibody-mediated enhancement of rabies virus

from J S Porterfield

THE long incubation period following naturally acquired rabies virus infection allows time for manipulation of the host's immune system in ways that can promote protection. Louis Pasteur's treatment of Joseph Meister was dramatically successful almost a century ago, and since then, very many others have benefited from rabies vaccines¹. There are, however, occasional failures, even when vaccine of established potency has been used, and much remains obscure about the pathogenesis of rabies virus infection, and about the precise way in which rabies vaccine confers protection. One puzzling effect, seen in both monkeys and mice immunized with rabies vaccine and subsequently challenged with rabies virus, has been termed the 'early death' phenomenon, since some vaccinated animals die sooner than non-vaccinated controls given the same challenge^{2,3}. Following earlier work which indicated that both bone marrow-derived B lymphocytes and thymus-derived T lymphocytes contributed to the clearance of rabies virus from the central nervous system^{4,5}, Prabhakar and Nathanson now present evidence, on p. 590 of this issue of *Nature*, that 'early death' in mice is mediated through antibodies, and is not a cell-mediated effect involving T lymphocytes, they do not, however, explain the mechanism whereby antibody produces this paradoxical response.

Apart from rabies, there are a number of other infections in which antibodies appear to produce effects which are detrimental to the host. The increased risk of severe bronchiolitis and pneumonia seen in infants who had been vaccinated with killed respiratory syncytial virus vaccine

and subsequently acquired natural infection with that virus is well documented, but still inadequately explained⁶. Dengue viruses normally produce a non-fatal illness with a rash, but a proportion of children in South-East Asia develop haemorrhagic manifestations and may die from shock⁷. Although the effector mechanism responsible for the shock remains controversial, several laboratory studies related to haemorrhagic dengue are relevant to the 'early death' phenomenon. Monkeys inoculated with dengue virus mixed with sub-neutralizing concentrations of anti-dengue antibodies show higher levels of viraemia than control animals given dengue virus only⁸. Dengue virus replicates poorly in normal human or monkey peripheral blood white cell preparations, but shows enhanced yields of virus when exposed to infectious virus-antibody mixtures⁹. This antibody-mediated enhancement of viral replication is not restricted to dengue virus, but has also been demonstrated in continuous cell lines of mouse and human macrophages with West Nile virus¹⁰, with other Togaviridae and Bunyaviridae¹¹. Halstead first suggested that the mechanism involved in the human monocyte system depended on an increased uptake of virus complexed with antibody through Fc receptors (present on these cells but absent from most other cells), the internalized virus escaping destruction by the phagocytes and replicating within them⁹. Using the simpler model system with mouse macrophage-like cell lines, Peiris *et al.*¹¹ showed that the antibody-mediated enhancement of West Nile virus replication was specifically blocked by monoclonal antibodies directed against Fc receptors on the cells they were using.

Are these findings at all relevant to the rabies 'early death' effect? Rabies viruses were thought to be serologically identical, but a number of rabies-related viruses are now known¹², and antigenic variation between rabies virus strains has been established¹³. Mice inoculated with Lagos Bat or Mokola viruses, two of the rabies-related viruses, and subsequently challenged with rabies virus, also died more quickly¹⁴. These findings suggest that it is not essential to have homologous neutralizing antibodies to produce the rabies 'early death' effect, but that cross-reacting sera may also be active in this system as in the dengue system^{10,15}. Three monoclonal antibodies directed against the envelope glycoprotein of West Nile virus will all enhance West Nile virus although only one of these has neutralizing activity¹⁶. Monoclonal antibodies against known components of rabies virus and against rabies-related viruses are available, and it would be of great interest to determine which of these was capable of producing the 'early death' effect with rabies virus.

It might be objected that rabies virus replicates in the central nervous system in cells that would not have Fc receptors, so that the mechanism of opsonization of virus-antibody complexes could not apply. Rabies virus is capable of replicating in a wide variety of different cell types in addition to neurones, and it is certainly possible that macrophages within the brain or spinal cord might support replication, following 'enhanced' uptake in the presence of anti-rabies antibodies, although experiments with mouse peritoneal macrophages lend little support to this view¹⁷.

These comments in no way detract from the unquestionable efficacy of present post-exposure treatments of rabies, which combine the use of human diploid cell vaccine with human rabies immune globulin¹⁸⁻²⁰. They emphasize a continuing need for investigation of the complex interactions involved in the pathogenesis of rabies virus infection. □

Antibodies, introns and biosynthetic versatility

from Miranda Robertson and Mike Hobart

SOON after the discovery that eukaryotic genes may be interrupted by non-coding DNA sequences, Gilbert¹ speculated in *Nature* that this unexpected arrangement might make it possible to produce variants of a single protein by differential splicing of the interrupted RNA. Specifically, he suggested that such a mechanism might underlie the well defined sequential changes that take place in the immunoglobulin molecule in the course of B lymphocyte ontogeny. As a result of these changes, a single antigen-binding site is associated successively with different effector sites to produce first immunoglobulin M, then immunoglobulin D, and later immunoglobulin G or sometimes A or E. Each of the different classes of immunoglobulin is expressed first as a membrane-bound receptor molecule and later, on the terminal differentiation of the lymphocyte, as a secreted protein which is identical to the receptor in all but a few residues at its carboxy terminal.

Both the class of the immunoglobulin molecule and whether it is membrane-bound or secreted depend on the structure of the constant region of its heavy chains (see Fig 1). Thus each heavy-chain variable region (V_H region) is associated in turn with a constant region (C_H region) coding for the μ , δ and γ , α or ϵ chains corresponding to IgM, IgD, IgG, IgA and IgE, and each of these chains may then undergo modification at its 3' end. It is now known that the class switch from IgM to IgG, IgA or IgE is mediated by translocation of the V_H region DNA with deletion of the C_H regions 5' to the one that is expressed². Deletion, however, cannot explain the switch from IgM to IgD, because some B cells, including a few tumour cell lines, synthesize IgM and IgD at the same time; nor is it an attractive explanation for the switch from membrane to secreted proteins,

Miranda Robertson is an associate editor of *Nature* and Mike Hobart is at the Medical Research Council Centre, Cambridge

Fig 1 Diagram of an antibody molecule showing the division of the heavy chains into the variable regions that determine antigen-binding specificity and the constant region domains. Each of the four domains, C_{H1} , C_{H2} , C_{H3} and the hinge, is encoded in a separate intron on the DNA. The sequences of the C_H introns are different for the different classes of immunoglobulin. The secreted form of each class (C_s) differs from the membrane form (C_m) in the last few carboxy terminal residues of C_{H3} ; the membrane form has a longer and more hydrophobic carboxy-terminal which anchors it in the membrane, the diagram shows the secreted version.

which are also simultaneously expressed. Instead, as Gilbert surmised, these processes are controlled by processing of the RNA.

Immunoglobulin D biosynthesis has become accessible to investigation through the work of Liu and his colleagues³ who have located the gene coding for the corresponding δ constant region. The gene itself is very peculiar, having only two constant region domains (instead of the usual three) and an abnormal hinge region. Furthermore, it lies only about 2,000 base pairs from the μ gene corresponding to the IgM constant region; this is a much shorter distance than has so far been found to separate other constant region genes, and it means a single stable transcript could be

made from the combined μ and δ coding regions. There is, indeed, now preliminary evidence for the existence of such a transcript⁴. The switch from μ to δ could thus be mediated by the removal of the entire μ gene as an intron (see Fig 2). The simultaneous expression of μ would be due to simultaneous production of shorter transcripts, ending before the δ sequences, or to polyadenylation at a site between the μ and δ genes.

This scheme has more recently been strongly reinforced by Moore *et al.*, who have confirmed the location of the δ gene in DNA both from mouse sperm and from a mouse hybridoma expressing membrane-bound forms of IgM and IgD, and established that the μ gene is not rearranged in the hybridoma DNA⁵. At the same time, however, they have raised the possibility that plasma cells committed to the secretion of IgD, unlike B cells transiently synthesizing the membrane form, may delete the μ sequences. So far, the evidence rests on a single rat plasmacytoma which secretes IgD and seems to have deleted the μ gene. Whether the deletion of μ is really a normal concomitant of the terminal differentiation of IgD-secreting lymphocytes, or whether it simply reflects the notorious instability of constant region genes in cultured cells, it is too early to say. It is not yet known, for example, whether the specialized switch sequences characteristic of the regions on the 5' side of the μ and γ genes² are to be found between the mouse μ and δ genes, but Rabbitts *et al.*⁶ have sequenced most of the region between the human μ and δ genes without discovering any.

The deletion or otherwise of the μ gene has, however, no direct bearing on the switch from membrane to secreted IgD, which is presumed to occur by the mechanism recently established for IgM. Independent observations by Alt *et al.*⁷ and Rogers *et al.*⁸ show that cells which are making both membrane and secreted IgM

Fig 2 Diagram of chromosomal DNA coding for IgM and IgD in a B cell. The open rectangles are exons and the intervening solid lines represent introns. Heavy vertical bars represent RNA splicing signals. In cells, expressing both membrane IgM and membrane IgD, it is believed that the entire region is transcribed. Dotted line *a* joins the introns that are spliced to produce membrane IgD, with the elimination of all the C_μ introns. Dotted line *b* joins the introns that are spliced to produce the membrane form of IgM. Note that if the switch from membrane to secreted IgM occurs through termination of transcription after the μ_s segment, transcription of the δ gene will also be shut off. The switch from membrane to secreted δ chains is believed to occur as described for μ .

contain μ chain messenger RNAs of different lengths. By examining cells in which the two forms of μ chain are synthesized in different proportions, Alt *et al.* were able to deduce that the longer of the two messages codes for the membrane (μ_m) form. Rogers *et al.* hybridized the two messages with cloned genomic DNA containing the μ gene, and found that while both hybridize the coding sequence of the four major μ domains, the longer one also hybridizes with a short segment on the 3' side. The same team went on to show⁹ that this short segment codes for a hydrophobic protein sequence whose characteristics are similar to those of known membrane-bound proteins.

Thus the secreted form of the protein (μ_s) is encoded by the four main μ gene segments, while the expression of the membrane form entails the addition of a further segment at the 3' side. This 3' μ_m segment has a sequence characteristic of a splice site at the beginning of an exon at its 5' end, but the matching splice sequence upstream occurs within the coding sequence of the C μ 4 domain, followed by the coding sequence for the last 19 amino acids of the μ_s chain and a termination codon. Early *et al.* suggest on the basis of this organization that μ_m , the first antibody to be synthesized by a B cell, is produced from a long transcript extending to a polyadenylation site beyond the μ_m coding segment. In the course of the processing of the transcript to mRNA the μ_s coding segment is eliminated as an intron, with the consequence that the termination codon is also removed.

When the B cell matures into an antibody-secreting plasma cell, either transcription terminates upstream of the μ_m segment or, for some reason, the μ_m segment is cleaved from the transcript. In either case the μ_s sequence is retained in the mRNA and read until the termination codon.

Thus the class switch from IgM to IgD seems to work by a mechanism analogous to that which operates the switch from μ_m to μ_s , and it has, incidentally, been pointed out that the μ_m - μ_s switch may automatically eliminate the production of IgD by IgM-secreting cells if transcription ends at the μ_s segment (see Fig 2).

The organization and regulation of the δ coding sequences open two further questions, the first specifically about the δ chain and the second generally about RNA splicing.

The first arises from the fact that the

coding sequences as described by Liu *et al.* can account for the shorter of the two known versions of the δ chain but not for the longer version¹⁰. However, further sequences apparently coding for the δ chain have more recently been detected (but not yet characterized)¹¹ further downstream, lending weight to the proposal of Liu *et al.* that differential splicing may provide a family of different δ chains with different — and it must be confessed entirely unknown — functions.

The second question is that of the mechanism by which introns are eliminated

from nuclear RNA. Until now, the simplest scheme — that the splice site at the end of each exon is paired with the matching sequence at the beginning of the next one downstream — has also been consistent with the known data. However, it plainly cannot account for the removal of the μ exons from the large μ - δ transcript. There is still a formal possibility that such a combined transcript does not exist, but if it does, it will clearly represent a further strong incentive to molecular geneticists of immunoglobulin to devise a splicing system that will work *in vitro*. □

Anomalous sputtering at high energy

from P K Haff and L E Seiberling

WHENEVER a sufficiently energetic stream of particles impinges on a target, there is some probability that target atoms and molecules will be knocked loose from the surface. This process of erosion on an atomic scale is called sputtering. For incident ions in the keV per AMU range, the average number of target particles ejected per ion is called the sputtering yield, S . Values of S in the range 1 to 10 are common. Quantitative calculations of the sputtering yield in this regime are based on the idea of a collision cascade (a primary recoil target atom makes collisions which produce secondaries which in turn produce tertiaries, and so on), and predicted yields typically agree with experiment to within a factor of 2 or 3.

At higher-incident ion energies, in the hundreds of keV per AMU to several MeV per AMU range, for example, the collision cascade predictions for the sputtering yield are small compared with unity. However, recent experiments using high-energy ion beams have shown that for some materials very large sputtering yields ($S \sim 4,000$ in some cases) exist when the collision cascade prediction is $S \ll 1$.

At Bell Laboratories, Walter Brown and his collaborators^{1,2} have shown that H and He in the 100 keV per AMU range can sputter H₂O ice at rates up to three orders of magnitude faster than those predicted according to the low-energy collision cascade calculations. Moreover, at temperatures below ~ 100 K, the yield is independent of temperature, and appears to be proportional to the square of the electronic stopping power, $(dE/dx)_e^2$. This is to be contrasted with the energy dependence of the collision cascade, which is given by the nuclear stopping power $(dE/dx)_n$ describing the energy loss of the projectile to elastic atomic collisions. Evidently energy is transferred from the initial electronic excitation into kinetic

energy of atoms, some of which escape as sputtered particles. Brown and his colleagues favour an explanation based on the ion explosion model. Neighbouring atoms, partially stripped of their electrons by the passage of the projectile, acquire kinetic energy through their mutual Coulomb repulsion. Such a picture leads essentially to a $(dE/dx)_e^2$ prediction for the energy dependence.

An early prediction³, that in certain dielectrics the ion explosion mechanism would lead to an anomalously high sputtering yield essentially proportional to $(dE/dx)_e^2$, led to a series of experiments in the Kellogg Radiation Laboratory at Caltech by Joseph Griffith⁴ and Elizabeth Seiberling⁵. These workers utilized beams of heavy ions (¹⁶O, ¹⁹F, ²⁰Ne) to bombard a dielectric target, UF₄. Sputtered ²³⁵U atoms were collected on mica, fissioned with thermal neutrons, and the resulting fission damage tracks in the mica counted to determine the yield S . This sensitive technique⁶ has allowed the Caltech group to determine the energy spectrum of sputtered particles as well as the dependence on bombarding energy. They discovered that, for ¹⁹F on UF₄, the excitation curve had a much steeper dependence on energy than $(dE/dx)_e^2$, and that the energy spectrum of sputtered particles was essentially thermal at a temperature of 3,500K. To explain their data Seiberling and co-workers have proposed a 'thermalized' ion explosion model, wherein Coulomb energy of neighbouring ion pairs is transformed into random thermal kinetic energy of atomic motion of particles located along the ion path. The model correctly gives the strong energy dependence of the yield, as well as the energy spectrum.

The discrepancy between the energy dependence of S , as measured by the two groups, does not necessarily mean that one is right and the other wrong. The assumptions underlying the thermalized ion explosion picture may breakdown for H and He bombardment where the ionization per unit length along the projectile track is considerably smaller than in the UF_4 experiments involving heavy ion projectiles.

Regardless of the precise nature of the mechanisms involved, enough has been learned to know that anomalous sputtering is probably quite important in the Solar System. Extrapolating Pioneer spacecraft data and the Bell Laboratories H_2O sputtering results, Lanzerotti and colleagues⁷ pointed out that over geological time significant erosion can be expected to have occurred on the icy satellites of Jupiter. They argued that up to 1 km of ice may have been lost to space, that interplanetary ice grains would be destroyed in tens of thousands of years by sputtering by the solar wind⁸, and that the ice particles comprising the rings of Saturn may be substantially affected by magnetospheric proton bombardment⁹. Work at Yale and Caltech has focused on the rate of erasure by sputtering of surface features, such as meteorite craters¹⁰, on the sputter-induced formation of planetary atmospheres¹¹, and on the albedo changes of icy satellite surfaces due to differential sputtering of ice and embedded silicate grains^{12,13} (which do not exhibit anomalous sputtering in the energy range considered).

It is clear that there are a large number of potential applications to problems in planetary science. The range of experiments reported so far, however, is relatively small, so, with theoretical ideas requiring further development, much uncertainty is attached to calculations of planetary processes. The Caltech energy spectrum suggests that energies of sputtered particles peak in the 0.3 eV range. This is substantially less than the energy required by, for example, an O atom to escape into space from Ganymede. Will H_2O exhibit a similarly soft spectrum? Probably it will, but until one can measure, or know enough of the mechanisms to estimate reliably, such quantities, it will be difficult to assess with confidence the detailed response of satellite surfaces to ion bombardment. □

Spinning asteroids

from David W. Hughes

ASTEROIDS spin with periods which usually lie between 5 and 12 hours although they can vary from 4 to 50 hours. The values are obtained from observations of fluctuations in brightness. Large variations are caused by gross changes in the projected cross-sectional area as seen from Earth (see the figure) and smaller variations by changes in the surface properties. Over longer time periods, of the order of a year or more, the light curve shape alters according to variations in the aspect angle — the angle between the line of sight and the asteroid's spin axis. Ideally these long-term variations should lead to an estimation of the asteroid's shape.

Problems arise when interpreting the results because too few asteroids have been observed and observational selection effects must be removed. These problems have been tackled by E. F. Tedesco (Lunar and Planetary Laboratory, University of Arizona) and V. Zappalá (Osservatorio Astronomico di Torino, Italy) in their recent paper in *Icarus* (43, 33, 1980).

About 2,150 asteroids are known and of these 321 have known spin periods. Tedesco and Zappalá divide these into two groups — 187 are members of families and the rest are main belt non-family asteroids. Previous studies in 1973 and 1979 were based on a total sample of only 64 and 182 asteroids respectively, so from this aspect alone Tedesco and Zappalá's work is a considerable improvement.

There are several fundamental selection effects in asteroid light curve data. Two main asteroid classes exist — C types which have a low albedo and are carbonaceous and S types which have a higher albedo and are siliceous or stony-iron in composition. Selection favours asteroids of high apparent brightness, which is equivalent to favouring the largest and nearest and the ones with highest albedo. Unfortunately the C to S ratio varies both as a function of size and distance from the Sun. Apollo and Amor asteroids are also unusual. These have orbits which cross those of Earth and Mars. Their mean rotational brightness amplitude is about 0.5 magnitudes while comparable-sized main belt asteroids have amplitudes usually less than 0.2 magnitudes. Members of the Appolo/Amor group are clearly more irregular and probably have a different evolutionary history to main belt asteroids. Another selection effect is inherent in the photographic photometry used to measure small asteroids. Usually observing periods of only 6 hours can be employed and variations of less than 0.2 magnitudes cannot be detected. Sixty per cent of the observed asteroids do not reveal their spins, indicating that the spin period is too long or the asteroid too regular. A further complication results from the fact that

many small asteroids were specifically selected for observation simply because they were members of Hirayama families. The family members have similar orbits and probably resulted from the fragmentation of a single parent. Removing the selection effects reduces the original data set of 321 to a final set of 134.

A theoretical light curve for a spinning asteroid showing how the brightness varies as a function of time. P is the period. The spin axis is perpendicular to the paper and the asteroid is viewed from B. Position A represents a fixed place on the asteroid.

Tedesco and Zappalá find that there is no clear-cut trend towards faster rotation for smaller objects. This is contrary to the conclusions of previous researchers who regarded collisional fragmentation as an important contributor to the modification of spin rates. While no definite relationship exists, the authors stress that the distribution is not entirely random. Asteroids larger than 175 km have a mean rotation period near 7 hours compared with a 10-hour period for smaller ones.

Considering asteroids with sizes between 75 and 175 km they found that the S asteroids have a mean period of 9.4 hours whereas the C asteroids have a period of 11.6 hours. The difference between these values is only 1.6 times the standard deviation and the authors conclude that this is too small and thus the spin rate is not a function of type.

How do asteroid shapes vary as a function of size and compositional type? It has been shown that the spin axes of asteroids are fixed in space and that it only takes about one million years to align the spin axis with the axis of maximum moment of inertia. Studies also indicate that asteroid surfaces generally lack variegation in colour or albedo. Unfortunately, shapes cannot be deduced directly from light curve amplitudes. Tedesco and Zappalá conclude that the very largest asteroids (diameter $D > 300$ km) have very low-amplitude variations (0.11 ± 0.02 magnitude). There seems to be

an abrupt increase in amplitude as the diameter decreases below 200 km (to about 0.21 ± 0.01). Even so, the shapes of smaller asteroids do not become significantly more elongated with decreasing size.

A search for possible collision-induced effects revealed that asteroids found in the zones of the asteroid belt which have low number densities do seem to have a higher value for the amplitude variation. Unfortunately the relative numbers of the specific asteroid types vary as one moves from zone to zone and this further complicates the picture.

When it comes to asteroid families it seems that the smaller members of the families have higher spin rates than normal. Larger family members ($75 < D < 175$ km) are virtually indistinguishable from non-family asteroids.

The significant conclusion of this investigation is that there is a pronounced

change in asteroid rotational properties at about 200 km. Asteroids larger than this seem to be primordial (at least in the sense that they are not remnants of a larger disrupted parent body), nearly spherical and probably have prograde rotation. Smaller asteroids have random spin axis orientations and the population contains a higher proportion of slowly rotating objects. It is interesting to note that the dividing diameter of 200 km is strongly evident when the frequency-size relationship of asteroids is investigated. The mass distribution index of asteroids changes at this diameter.

Future progress in the study of asteroid spin statistics and the effect of collisional evolution depends on the acquisition of more data. The picture will be a lot clearer if the number of asteroids with accurately measured spin periods could be increased by a factor of two or three. □

Production and processing of prolactin

from Alan D B Malcolm

THE pituitary hormone prolactin (PRL) was for many years something of an enigma. Its similarity to growth hormone both chemically (human PRL and human GH have 40 per cent of their amino acids in common) and biologically (in lower mammals PRL acts as a growth hormone) meant that its very existence in humans was disputed. Advances in protein purification and radioimmunoassay have now resolved this question and we are beginning to understand something about the factors controlling its synthesis and breakdown. Controls seem to exist at many stages including transcription, RNA processing, translation, preprolactin processing and secretion together with nuclease degradation of RNA and proteolytic attack on the various polypeptides.

The mRNA for rat PRL was obtained by extracting the poly(A)-containing RNA from the pituitary after stimulation of the rat with diethylstilboestrol (Gubbins *et al* *Nucleic Acids Res* 6, 915, 1979). This RNA was used to produce cloned copy DNA, which has since been used to identify genomic PRL sequences in a rat genome 'library'. The PRL gene contains four intervening sequences (Chien and Thompson *Proc natn Acad Sci U S A* 77, 4583, 1980), one of which occurs in the 5'-untranslated region. The sequence of one of the genomic clones (Gubbins *et al* *J biol Chem* 255, 8655, 1980) shows that some of the intron sequences are repeated elsewhere in the rat genome. It is interesting that although the coding lengths of PRL and GH are similar and they both have four introns, the lengths of the introns are much

greater in PRL than in GH. The total length of the PRL 'gene' is therefore 10 kilobases compared with only 2.1 for GH.

Maurer and his colleagues (*J biol Chem* 255, 2243; 1980) have approached the problem of transcription and processing of PRL RNA by isolating RNA from the nucleus and cytoplasm of pituitary cells. The RNA was then electrophoresed through an agarose gel and transferred to diazobenzylxymethyl paper. Hybridization of the now immobilized RNA to ^{32} P-labelled cDNA revealed the presence of five PRL bands (7.0, 6.4, 3.8, 1.7 and 1.0 kilobases) in nuclear RNA but only one (1.0 kilobase) in cytoplasmic RNA. Presumably the different nuclear RNA species arise from ordered removal of the introns.

The secretion of all the pituitary hormones is controlled by the hypothalamus. In the case of PRL, dopamine is probably an important inhibitory factor and many dopamine agonists, such as the ergot alkaloids ergocryptine (EC) and its synthetic congener bromoergocryptine (BEC), will reduce overall PRL production. EC is used clinically to reduce PRL levels in spite of slightly unpredictable side effects (*New Engl J Med*, 302, 749, 1980).

To investigate the stage at which EC regulates PRL production, Maurer (*J biol Chem* 255, 8092, 1980) has studied the decrease in both *de novo* PRL synthesis

and PRL mRNA in cultured pituitary cells after treatment with EC. The very good correlation between the two suggests that EC acts either at transcription, RNA processing or RNA breakdown. It is slightly odd that the decreases occur over 20–100 hours which suggests that the mRNA may have a fairly long half life. Interestingly though, EC affects PRL specifically (no other pituitary hormones are affected) and is 100 times more effective than is dopamine.

This picture is, however, somewhat confused by the finding that BEC increases the rate of breakdown of the hormone itself (Dammes and Rudnick *J biol Chem* 255, 2776, 1980). Maurer (*Biochemistry* 19, 3573, 1980) suggests that BEC blocks PRL secretion by the cells and the subsequent accumulation inside the cells results in increased proteolysis by lysosomal enzymes. The fact that chloroquine (which reduces the rate of appearance of lysosomal enzymes in the cytoplasm) partially reverses this effect of BEC favours such an interpretation.

Hormone production can also be prevented by incubating the pituitary cells with hydroxynorvaline — an analogue of threonine which can be incorporated into protein. Normal processing of preprolactin to PRL involves cleavage at the bond between residues 30 (normally threonine) and 31. Apparently the processing enzyme cannot hydrolyse this bond when threonine is substituted by hydroxynorvaline because the prehormone accumulates in the analogue-treated cells (Hortin and Boime *J biol Chem* 255, 7051, 1980).

Rossier and colleagues (*Proc natn Acad Sci U S A* 77, 666, 1980) have shown that stress induces PRL synthesis and they believe that this arises from the stress-induced production of opiate peptides which are known to increase PRL levels.

More recent results (Denef *et al* *Nature* 285, 243; 1980) have suggested that the action of dopamine is not quite as simple as was previously thought. Although high levels ($\geq 1 \mu\text{M}$) of dopamine do indeed reduce PRL, at much lower levels ($\leq 1 \text{ nM}$) dopamine actually stimulates PRL production.

The nature of the interactions between prolactin and the steroid hormones is still not clear. Although oestradiol seems to stimulate PRL production, its metabolite, 2-hydroxyoestrone, produces a rapid decrease in PRL levels (Fishman and Tulchinsky *Science* 210, 73, 1980). The hydroxylating enzyme is inhibited by the opiate agonists which stimulate PRL release and is activated by antagonists which suppress PRL. This means that *in vivo* the opiates may affect PRL levels by their effect on the enzymes which metabolize the steroid hormones.

Clearly we still have some way to go in our attempts to understand how the levels of this interesting molecule really are regulated. □

Tropical soils and agrotechnology transfer

from Ian Smalley

MORE food needs to be produced in the third world, in the countries which are grouped in the tropical regions. But the soils of the tropics often have a 'variable charge' character which makes them sufficiently different from most soils of the temperate regions that research in the developed world can not be directly applied. The transfer of agriculture technology between the developed and the developing world can thus encounter fundamental problems.

Various aspects of variable charge soils, and in particular the problems of classification and of transfer of agricultural technology, were discussed at a recent meeting* at Massey University in New Zealand. In variable charge soils the electrical charge on the particle surfaces, both in magnitude and sign, can vary greatly with changes in the pH, ionic strength and composition of the soil solutions. The variable charge nature of the soils arises from the abundance, in the clay fraction, of minerals having amphoteric (positive or negative) surfaces. Prominent among such minerals are the oxides and hydrous oxides of aluminium and iron which may be crystalline, paracrystalline or poorly ordered. The 1:1 type layer silicates, such as halloysite and kaolinite, also show amphoteric properties, associated with their relatively large exposed crystal edge surface. On the other hand, the negative surface charge of 2:1 clay minerals arises from extensive isomorphous substitution within the structure and hence is largely independent of pH. Thus soils rich in micaceous and similar minerals are said to be of constant or permanent charge.

Besides having amphoteric surfaces, clay-size mineral constituents with variable charge generally have a low capacity to adsorb or retain nutrient cations in the range of pH and ionic conditions which prevail in natural soil systems. For this reason, these constituents have been grouped together and referred to as 'low activity clays'. Thus, soils rich in low activity clays are, in general, naturally infertile and this causes a major problem in tropical agriculture. Although the amphoteric nature of some soils and soil constituents has been recognised for a long time, it is only relatively recently that its importance, in terms of soil processes and management, has come to be appreciated. This is because soil research, as carried out in the developed countries of Europe and North America, has largely been directed to understanding the behaviour of temperate soils, many of which are of the

constant charge type. The variable charge constituents, if they were not altogether ignored, were often regarded as contaminants and removed from the system.

A common constituent of volcanic variable-charge soils is the clay mineral allophane (now widely believed to have a spherical structure see *News & Views, Nature*, 281, 339, 1979). Recent studies on allophane in New Zealand soils were reported by R. Parfitt (NZ Soil Bureau). Allophane has been defined as a series of naturally occurring hydrous aluminosilicate clays, characterised by short range order and by the predominance of Si-O-Al bonds, and it appears to be made up of hollow spherules 3.5–5.0 nm in diameter. Spherules with a molar ratio close to Al/Si = 2.0 from Mt Egmont andesitic pumice have the proto-imogolite infrared spectrum. This, together with X-ray fluorescence, pyridine adsorption and silicate analysis data, indicate that the wall of the allophane spherule is made up of imogolite segments. The fine tubular crystals of imogolite are also found in New Zealand soils.

Allophane (Al/Si = 2.0) occurs in several different environments in New Zealand. It is the dominant clay mineral in an Egmont soil formed from andesitic ash, in a Taupo soil formed from rhyolitic Taupo pumice, and in a Maoroa soil formed from rhyolitic ash. In rhyolitic ash, allophane (Al/Si = 2.0) is the dominant clay mineral where the annual rainfall exceeds about 1,600 mm. Where the annual rainfall is less than 1,600 mm, allophane and halloysite are the dominant clay minerals, with allophane decreasing and halloysite increasing in older tephra. Halloysite is the dominant clay mineral in a Kereone soil, where the rainfall is 1,200 mm.

Allophane soils present a problem for mechanical analysis and clay recovery because at field pH or in acid media the positively charged allophane flocculates with any crystalline clay present by charge interaction, and in alkali or calgon solution it is self-flocculating by some unknown mechanism. Studies of Scottish allophanic subsoils by H. J. Fullerton (University of Glasgow) showed that these behave like New Zealand allophane soils in that they flocculate by charge interaction when vibrated in water and continue to flocculate at all alkali pH values. Unlike allophane soils, however, they deflocculate in calgon solution. Alkaline flocculation appears to be not a rare property confined to allophane, but a common property of disordered clay surfaces.

The major technology transfer project discussed, the Benchmark Soils Project, is being applied to three soil types across the tropical world. Three different soil families have been chosen for experimentation: the

clayey, kaolinitic, isohyperthermic Tropeptic Eutrustox (the terminology of the USDA-developed 'soil taxonomy' system is used), the thixotropic, isothermic Hydric Dystrandepts, and clayey, kaolinitic, isohyperthermic Typic Paleudults. These soil families represent three different agroclimatic zones: dry and warm (the Eutrustox), moist and cool (the Dystrandepts), and moist and warm (the Paleudults). The soils all have distinct variable charges which influence soil management and utilization. G. Uehara (University of Hawaii) reported that technology transfer in 15 separate areas was being attempted, among these were selection of tree crops for windbreak, fuelwood and erosion control, susceptibility of salinization, and soil workability and trafficability.

The Benchmark Soils Project comprises two companion research contracts awarded to the Universities of Hawaii and Puerto Rico in 1974 and 1975 by the US Agency for International Development. The primary objective of the project is to test the hypothesis that agro-production technology, particularly soil management experience, can be transferred among tropical countries on the basis of soil families as defined in the system of soil taxonomy. The project has established a research network that includes 23 experimental sites in Brazil, Cameroon, Hawaii, Indonesia, the Philippines and Puerto Rico. The basic research strategy is to select soils belonging to the same soil families in widely separated geographical areas, subject these soils to identical and standardized experiments, and correlate the plant yields. The transfer experiments are complemented by pragmatic management experiments and variety trials intended to expand the basic knowledge of crop production for each soil family.

R. L. Fox (University of Hawaii) pointed out that in their attempts to replace the humus theory of plant nutrition with the inorganic nutrient theory, early naturalists assumed that it was only necessary to replace the nutrients removed in the harvest. Phosphate reversion, K fixation, denitrification, soil erosion and leaching of nutrients were not sufficiently recognized. We now know that a soil fertility programme that is content with returning nutrients exported in the harvest is not sufficient at all. This fundamental mistake has been repeated almost endlessly during the past century — most recently in the tropics. Nowhere are the consequences likely to be so acute as on the weathered, variable charge soils which are abundant there. □

Interfering plants

from Peter D. Moore

IN his classification of competitive strategies, Miller (*Adv ecol Res* 4, 1, 1947; and *Brookhaven Symp Biol* 22, 63, 1969) recognizes two major categories, exploiters and interferers. The interferer has a large body size, a long generation time and is relatively independent of physical environmental factors. Rather than evolving efficient mechanisms for resource exploitation, they substitute space for the resource and succeed by means of their capacity for the physical exclusion of potential competitors from the resource. The concept was developed largely with certain vertebrate animals in mind, especially those exhibiting territorial behaviour.

There are also some members of the plant kingdom which deserve the title 'interferers'. In particular, those which assume dominance in stable ecosystems have characteristics which correspond to those of the interferer. The substitution of space for a resource may be achieved purely by physical growth, or may be achieved by more subtle means. The production of chemical inhibitors which curtail the growth of plant individuals of either the same or another species is one such mechanism. Even more subtle is the process described by Rice and Pancholy (*Am J Bot* 59, 1033, 1972, see also *Nature* 254, 184, 1975) in which toxins from litter of grassland climax dominants is considered to inhibit the process of nitrification (the conversion of ammonium ions to nitrate in the soil) by suppressing the activity of the soil microbes *Nitrobacter* and *Nitrosomonas*. Such a strategy would reduce the rate of nitrogen recycling and thereby slow down further ecosystem growth and vegetation succession.

This attractive and sophisticated

interference technique has, however, received little supporting evidence over the past few years. It is difficult to distinguish between direct chemical suppression and rather more complex interactions involving the depletion of other necessary resources (for example, phosphorus) or the overall reduction of pH, both of which could influence the rate of nitrification. Jordan, Todd and Escalante have tried a technique of manipulative experimentation in the Amazonian rain forest (*Oecologia* 39, 123, 1979). They added calcium carbonate to the thick root mat on the forest floor and checked the leachate for nitrogen losses. They observed an enhanced loss of nitrogen, but it was mainly in the form of ammonium ions, so the treatment had not stimulated nitrification. They also noted that the pH of the drainage water was still as low as 4.5 and thus concluded that it was the low pH of the soil which was inhibiting the activity of the nitrifying bacteria. However, they conceded that, since the leachate had the colour and consistency of tea, it could be the tannin from the leachate which was responsible for the suppression.

The deciduous forests of Missouri have provided opportunities for further analysis of the curtailment of nitrification. Here Lodhi (*Am J Bot* 64, 260, 1977, 65, 340, 1135, 1978) has shown a heterogeneous pattern in the nitrogen levels of soils under different canopy tree species. Ammonium ion concentrations were invariably higher than nitrate levels, the degree of excess being related to canopy species. Also, there was an inverse relationship between am-

monium ion concentration and the density of nitrifying bacteria in the soils. Under some trees, such as American elm (*Ulmus americana*) and sycamore (*Platanus occidentalis*), the soils were of neutral pH, so one cannot resort to a low pH explanation for the suppression of nitrification at all these sites.

Lodhi has now backed up his contention that polyphenolic compounds can be involved in these woodland inhibition observations by his studies with Killingbeck (*Am J Bot* 67, 1423, 1980) on the ponderosa pine stands of North Dakota. Here the soil pH is neutral to slightly alkaline (mean pH 7.25 in the A horizon and 7.75 in the C horizon). Once again, the ammonium ions considerably exceed nitrate ions and the population of *Nitrosomonas* and *Nitrobacter* were low. He then added various extracts of ponderosa pine needles and bark to experimental cultures of these microbes and found that maximum inhibition of their activity (93 per cent) was achieved with aqueous extracts of the needles or with mildly alkaline soil hydrolysates. Both of the extracts were rich in condensed tannins, which probably accounted for the inhibition.

Nothing is known of the mechanism of nitrogen uptake by ponderosa pine but Lodhi speculates that there would be considerable ecological advantages in its taking up ammonium rather than nitrate ions. In this way leaching losses of nitrogen would be reduced, energy would be conserved and the tree would benefit in terms of competition for the soil nitrogen resources. More data is required before such speculations can be confirmed but, should they prove correct, *Pinus ponderosa* will effectively fit the Miller criteria defining an interferer. Whilst satisfying its own requirements, it denies other organisms access to the soil nitrogen resource by allelochemic inhibition of nitrification. □

THE NEW MUSEUM OF NATURAL HISTORY

The great terra-cotta building facing Cromwell Road, South Kensington, and occupying the site of the old 1862 Exhibition, about which for the past twelve months public curiosity has been raised, is about to draw up its blinds, and offer a part of its extensive galleries for inspection on Easter Monday.

It is no secret that for thirty years past the accommodation in the British Museum, Great Russell Street, Bloomsbury, "both for man and beast," had become too restricted, and the necessity for a larger building was keenly felt. As usually happens in such cases, the most adventurous and energetic officer was the first to obtain for his department what he

required, namely, *more room*.

Sir A. Panizzi (then Keeper of Printed Books) projected, shortly after the 1851 Exhibition, his scheme for a great central Reading-room and Library, and some years later on, the Department of Antiquities, represented by Mr C. T. Newton, C.B., also obtained an addition to its galleries on the western side, and still more recently on the southern side, next to the great Entrance Hall.

Great praise is due to Mr Bond, the present Principal Librarian, for putting an end to the use made of the fine colonnade in front of the British Museum, which for twenty-five years was blocked by antiquities covered in with a row of extremely unsightly and incongruous wood and glass sheds. These are now happily removed. The Department of Prints and Drawings lacking a gallery, obtained possession of the "King's Library" floor on the east side for an exhibition space, and even the conservative Coin Department likewise laid out for the public a few show-cases here of coins and medals.

But, like the clothes of the rising son, in the old caricature, the collections everywhere had outgrown their receptacle, and none more so than the departments of Natural History. Scientific men were however not unanimous, and a fierce controversy was carried on in 1858-59 as to the relative merits of enlargement on the old site, or dismemberment. Finally, after a Committee of the House of Commons

Erratum

In *A tropical Volute shell and the Icarus syndrome* from Jonathan C. Howard (*News and Views* April 9, 290, 441, 1981) 'simulate' was incorrectly printed as 'stimulate' on p442, column 3, line 37. The correct sentence reads "C. H. Waddington⁸ pointed out as long ago as 1942 that genetic modifications to adaptable systems can simulate the inheritance of acquired characters."

had taken evidence upon the subject, the removal of the Natural History Collections was decided upon by the Government.

But the death of the Prince Consort, the delay of the House of Commons to vote the necessary funds, the retirement of Sir A. Panizzi from the post of Principal Librarian, the discussion of rival plans, the inevitable delays about the completion of any Government building, caused twenty years to pass before the plans of the chosen architect, Mr Alfred Waterhouse, were realised in a solid and material form.

REVIEW ARTICLE

Dynamics, diffusion and geomorphological significance of tidal residual eddies

J. T. F. Zimmerman

Netherlands Institute for Sea Research, PO Box 59, Texel, The Netherlands

Many shallow tidal areas show the occurrence of ebb and flood surpluses, organized in cell-like structures or 'tidal residual eddies'. They seem to arise from a nonlinear transfer of vorticity from the oscillating tidal field to the mean field, the irregular structure of the bottom topography or the coastline acting as a catalyst to produce the necessary vorticity gradients. The dynamical characteristics of the eddies assist our understanding of the geomorphology of the sea bed.

VAN VEEN'S review¹⁻³ of the hydrography of the Straits of Dover and its influence on the morphology of the Dutch coast stimulated much research on the connection between tidal currents and a variety of coastal geomorphological features. Much attention has since been given to the occurrence of linear or parabolic sand ridges in tidal areas, such as the Flemish Banks in the Southern Bight of the North Sea. We now know that nearly all shallow tidal areas where oscillating currents exceed some critical speed (0.5 m s^{-1}) and where sand is present, are sites at which these ridges can be found (see Fig. 1)⁴. Tidal currents in the vicinity of these ridges are generally asymmetrical in that at some places more water seems to be displaced in the direction of the flood current (a flood surplus) whereas the reverse occurs elsewhere (an ebb surplus). These surpluses, called residual currents, are often organized in cell-like structures or 'residual eddies' (see Fig. 2). Yet, although these features have long been recognized, the underlying physical dynamics of residual eddies in connection with tidal sand ridges have only recently become understood.

The dynamics of residual eddies occurring in geomorphological conditions other than tidal sand ridges, such as the generation of residual eddies by headland promontories or by

narrow tidal inlets along the coast and the organization of ebb and flood surpluses by the gross geometry of half-enclosed tidal embayments, have also been extensively investigated. Although, at first sight, it seems that different mechanisms are at work in each geomorphological setting, it is shown here that the formation of residual tidal circulation can in each case be understood as a transfer of vorticity from the tidal oscillating current velocity field to the mean (residual) field, though the way in which tidal vorticity and tidal vorticity gradients are produced in the first instance differ.

Although we now have a good understanding of the fluid dynamical response of an irregular sea bed or coastline to the tidal current regime, we are still far from having a satisfactory theory for the interaction of tidal currents and morphological structures concerned, that is, a complete explanation of how the morphology is both being shaped by, and gives shape to the current velocity field. However, the recently developed physical description of tidal residual circulation gained by observations in the field, by hydraulic or numerical modelling and, principally, by theoretical analysis may provide a basis for such a theory and may also help our understanding of the contribution of residual eddies to diffusive transport processes in tidal areas.

Fig 1 The worldwide distribution of tidal current ridges according to ref. 4

Fig. 2 A string of current meters produces, after averaging the instantaneous velocity $\mathbf{u}(t)$ over a tidal cycle, residual current vectors ($\rightarrow$) tangential to which a residual streamline $\mathcal{L}$ is drawn. The instantaneous velocity vector can be decomposed into a component $\mathbf{u}_{\parallel}$ tangential to $\mathcal{L}$ and a component $\mathbf{u}_{\perp}$ perpendicular to $\mathcal{L}$.

Vorticity dynamics

The relevance of vorticity to residual eddy dynamics can readily be appreciated if the concept of circulation, which can easily be visualized and has a close connection with vorticity, is introduced as a measure of eddy strength.

Figure 2 shows a hypothetical string of current velocity meters in a quasi two-dimensional (horizontal) tidal velocity field. A simple time-dependent velocity field is assumed. At each position the velocity has two components: one which is strictly periodic in one of the basic tidal frequencies, σ , and the other is a time-independent residual. The current meters are supposed to produce non-vanishing residual-velocity vectors (tidal averages), tangent to which a curve $\mathcal{L}$ is drawn. The curve itself represents a residual streamline, its shape suggests the presence of a residual eddy in the field. The instantaneous velocity vector at each point of $\mathcal{L}$ is

$$\mathbf{u}(t) = \mathbf{u}_{\parallel}(t) + \mathbf{u}_{\perp}(t) \quad (1)$$

where $\mathbf{u}_{\parallel}$ and $\mathbf{u}_{\perp}$ are components tangential and perpendicular to $\mathcal{L}$ respectively. Denoting tidal averaging by $\sim$, we have by definition of $\mathcal{L}$ and in view of the simple time dependence of the velocity field

$$\begin{aligned} \tilde{\mathbf{u}}_{\perp} &= 0, \quad \tilde{\mathbf{u}}_{\parallel} = \tilde{\mathbf{u}} \\ \mathbf{u}_{\perp} &= \mathbf{u}'_{\perp} \sin(\sigma t + \phi_{\perp}), \quad \mathbf{u}_{\parallel} = \tilde{\mathbf{u}}_{\parallel} + \mathbf{u}'_{\parallel} \sin(\sigma t + \phi_{\parallel}) \end{aligned} \quad (2)$$

where $\phi_{\perp}$ and $\phi_{\parallel}$ are arbitrary phase angles. To get some measure of the eddy strength, the circulation, C , around $\mathcal{L}$ is now defined by the contour integral

$$C(t) = \oint \mathbf{u}(t) \cdot d\mathbf{l} = \oint u_{\parallel}(t) dl \quad (3)$$

By Stokes' theorem this integral equals an integral over the surface A enclosed by $\mathcal{L}$

$$C(t) = \iint_A \omega \, dA \quad (4)$$

where ω , the vorticity of the current velocity field, can be interpreted as the 'spin' or twice the angular velocity around a

vertical axis of an infinitesimal fluid element inside $\mathcal{L}$. Now, taking tidal averages, the residual circulation reads

$$\tilde{C} = \oint \tilde{u}_{\parallel} dl = \iint_A \tilde{\omega} \, dA \quad (5)$$

Thus, if residual circulation around a closed curve in a tidal area is positive (anticlockwise or cyclonic) or negative (clockwise or anticyclonic) then, on average, a distribution of negative or positive residual vorticity ('spin') of the fluid elements inside the area exists over the area enclosed by the curve.

To find when tidal regions exhibit areas of non-vanishing tidal average vorticity we need to look more closely at the equation of motion of a quasi two-dimensional homogeneous fluid flow in a rotating frame of reference

$$\frac{\partial \mathbf{u}}{\partial t} = -\{f + \omega\}(\mathbf{j} \times \mathbf{u}) + \nabla(g\zeta + u^2/2)$$

local acceleration =

Coriolis + vortex force + dynamic pressure gradient (6)

$$-\frac{r}{D} \mathbf{u} + \nu \nabla^2 \mathbf{u}$$

(linearized) bottom friction + horizontal turbulent momentum exchange

The local acceleration at a particular position in the field equals the sum of the forces in the right-hand side of equation (6), f denoting the Coriolis parameter (the planetary vorticity), g , the acceleration of gravity, ζ , the departure of the sea surface from its mean position, r , a bottom friction parameter, D , the water depth, and ν , a turbulent viscosity coefficient. Neglecting the last term in equation (6) the equation of motion is readily transformed into an equation for the circulation around $\mathcal{L}$, which reads

$$\frac{\partial C}{\partial t} = \oint (f + \omega) u_{\perp} dl - \frac{r}{D} C \quad (7)$$

The residual circulation is obtained by averaging equation (7) over a tidal cycle

$$\begin{aligned} \tilde{C} &= \frac{\oint \overline{\omega(t) u_{\perp}(t)} dl}{r/D} = \\ &= \text{tidal mean flux of vorticity through } \mathcal{L} \\ &\quad \times \text{relaxation time scale of bottom friction} \end{aligned} \quad (8)$$

Thus a non-zero (residual) circulation around $\mathcal{L}$ is produced if, when averaged over the tidal cycle, there is a net flux of vorticity into the region enclosed by the curve (a net outflux is equivalent to a net influx of vorticity of opposite sign). Such 'pumping' leads to the build-up of positive or negative residual vorticity, ultimately balanced by the dissipation due to bottom friction, or, had we included that effect in equation (7), to horizontal turbulent vorticity diffusion. Note that $\oint \omega u_{\perp} dl$, having dimensions $[L^2 T^{-2}]$, can be interpreted as a stress (momentum flux), often called the 'tidal stress'^{5,6}. Hence the residual vorticity flux can be thought of as the analogue of a time-independent tangential stress exerted along the boundary of the water column inside $\mathcal{L}$, which therefore tends to spin-up.

For a non-vanishing residual circulation we need to both produce vorticity somewhere in the field and achieve a net flux of vorticity through a closed curve over a tidal cycle. Thus, whereas the condition necessary for residual circulation, expressed by equation (8), is now revealed physically, how does such a net flux arise? Mathematically, if $u_{\perp} \propto \sin(\sigma t + \phi_{\perp})$ and $\omega(t) \propto \sin(\sigma t + \psi)$, it is the phase difference $\phi_{\perp} - \psi$ that determines sign and magnitude of the pumping term $\oint \omega u_{\perp} dl$. If $\phi_{\perp} - \psi$ is near to 0 or π that is if $u_{\perp}$ and ω change sign approximately at the same moment in the tidal cycle, then conditions are favourable for the

buildup of residual vorticity. Figure 3 indicates when such favourable conditions are met, summarizing the different situations dealt with recently. We classify these situations according to the geomorphological background.

(1) Residual basin circulation (Fig. 3a, refs 7–9) is the simplest example of tidal residual circulation and is given by the distribution of ebb and flood surpluses, generated by frictional boundary layers in a semi-enclosed basin. In such a basin the tidal-current velocity diminishes both towards the back wall and, by friction, towards the side walls. By the latter process vorticity is generated, the sign of which is opposite at both sides of the basin and changes with the current direction. As the tidal current decreases towards the back wall, at the left-hand side of the basin, during the flood, more anticlockwise vorticity is brought into the heavily drawn curves near the entrance than is transported outwards near the back wall. During the ebb more clockwise vorticity is brought out, which is equivalent to an influx of anticlockwise vorticity. Thus, averaged over the tidal cycle there is a net influx of anticlockwise vorticity resulting in an anticlockwise residual circulation along the heavily drawn curve in the left-hand side of the basin. The opposite occurs on the right-hand side where a clockwise residual circulation is set up. Thus a flood surplus exists in the middle of the basin and an ebb surplus along the sides.

(2) Headland eddies (Fig. 3b, refs 10–12)—along a coastal promontory the tidal flow is accelerated and decelerated in the current direction and has a maximum near the headland. Concurrently a frictional boundary layer develops diminishing the current velocity towards the coast. Thus vorticity is produced along the coast with its sign alternating between the ebb and flood stages of the tide. As the vorticity is largest near the headland there is a net flux of clockwise vorticity into the upper heavily drawn curve and out of the lower one when the current direction is upwards, during the flood, for example. During the ebb, the situation does not reverse because of a net flux of anticlockwise vorticity out of the upper curve and into the lower curve, which is equivalent to the situation during the flood. Hence there is a net flux of clockwise vorticity into the upper curve and of anticlockwise vorticity into the lower curve, giving rise to a vortex pair of opposite sign at both sides of the promontory.

Note that by placing at the left-hand side of Fig. 3b its mirror image, a quadruple vortex system is obtained which represents

the situation close to a sudden narrowing of a tidal channel, as often occurs near inlets connecting tidal channels and the open sea.

(3) Sand ridge eddies (Fig. 3c/d, refs 13–16)—when a tidal current crosses a submarine sand ridge, the flow is accelerated going up the slope and decelerated going down the slope. Consequently a water column experiences a slightly higher Coriolis force on its shallower side than on its deeper side. Thus a 'Coriolis torque' exists on the column having opposite sign at both sides of the ridge, and, at the same side, at both stages of the tidal period. A torque is also produced by bottom friction, the latter being stronger at the shallower side of a fluid column. Both torques reinforce each other if the ridge is inclined anticlockwise with respect to the tidal current (Fig. 3c), whereas they counteract in the opposite case (Fig. 3d). Taking a curve around the ridge, it is obvious that in case (c) there is a net influx of clockwise vorticity or, equivalently, an outflux of anticlockwise vorticity produced by both torques during the flood (current velocity upwards), assuming that vorticity production is quasi-static, that is the instantaneous sign of vorticity is the same as that of the applied torque. The same occurs during the ebb (current velocity downwards), so that a residual influx of clockwise vorticity produces a clockwise residual circulation around the ridge. In case (d) the same applies to residual circulation related to vorticity production by Coriolis torques but the reverse applies to the residual circulation produced by bottom frictional torques, the latter now giving rise to anticlockwise residual circulation. As both mechanisms counteract, a weaker net circulation may be expected compared with case (c). Of course, this applies to situations in the Northern Hemisphere. In the Southern Hemisphere ridges inclined clockwise with respect to the tidal current would be expected to show reinforcing of both mechanisms.

Scale effects

Are residual eddies of all sizes equally probable or are eddies of a specific horizontal extent preferred dynamically? This question, relevant to the geomorphology of the sea bed, has only previously been answered^{14, 15} for the production mechanisms shown in Fig. 3c, d, that is residual eddies produced by depth gradients in the open sea. Consider a test topography (Fig. 4a) consisting of a regular series of humps and bumps with a height or depth h below the mean depth H and a horizontal wavelength

Fig. 3 The basic production mechanisms of residual circulation in tidal currents through sidewall friction (a, b) or through Coriolis and bottom frictional torques (c, d). a, Rectilinear tidal currents in a semi-enclosed basin are shown by solid arrows for the flood period and dashed arrows for the ebb period. The currents decrease both towards the end of the basin and towards the side walls. Vorticity generated by side-wall friction is shown by solid circles for the flood period and dashed circles for the ebb period. The vorticity has opposite signs at both sides of the basin and diminishes towards the back wall. The resulting residual circulation is shown by heavy streamlines. b, Tidal currents, tidal vorticity and residual circulation in the neighbourhood of a headland promontory have the same symbols as in a. Tidal currents are largest near the headland and decrease towards the coast. Tidal vorticity therefore has a maximum near the headland. c, d, A submarine sand ridge is shown by ellipsoidal dashed depth contours, + represents the top of the ridge. Rectilinear tidal currents, solid arrows for the flood period, dashed arrows for the ebb period, cross the ridge, which in c is inclined anticlockwise with respect to the current and clockwise in d. By the presence of bottom depth gradients both the Coriolis force and bottom friction produce torques at a fluid column as shown by the open arrows for the former and solid arrows for the latter. The situation during the flood period is only shown for the left-hand side of the ridge and during the ebb period only for the right-hand side. The bottom frictional torques change sign if the inclination of the ridge changes from anticlockwise to clockwise, whereas the Coriolis torques remain unchanged. The resulting residual circulation around the ridge is shown by solid and open arrows, parallel to the depth contours, the arrows denoting respectively circulation produced by the bottom friction mechanism and by the Coriolis mechanism.

L The tidal current is characterized by a velocity amplitude U and the frequency σ , which produce a length scale, the amplitude of horizontal tidal excursion, l

$$l = U/\sigma \quad (9)$$

Together, tide and topography are now characterized by two non-dimensional parameters, a relative depth h/H and a wavenumber, λ

$$\lambda = \frac{2\pi l}{L} = \frac{\pi \times \text{tidal excursion}}{\text{topographic wavelength}} \quad (10)$$

The ratio v of the residual speed around a curve enclosing a

hump and the amplitude of tidal velocity is^{14 15}

$$v \equiv \frac{\bar{u}}{U} = \frac{h}{H} g(\lambda) \quad (11)$$

The weighting function $g(\lambda)$ is shown in Fig 4b for both vorticity production mechanisms—Coriolis and bottom frictional torques. An interval of length scale ratios centred around $\lambda \approx 1$ leads to a strong resonance in terms of residual tidal velocity. The latter falls off rather rapidly for both smaller and larger length scale ratios. This is because for very large topographic length scales vorticity gradients in the field vanish, so that no net flux of vorticity into a closed curve can be produced. For very

small length scales fluid columns experience during the tidal cycle such a rapid sign reversal of the vorticity production mechanisms that effectively no vorticity can be built up, so that no vorticity can be transferred to the mean field. The 'resonance peak' is reflected in the asymptotic behaviour¹⁵ of $g(\lambda)$

$$\begin{aligned} g(\lambda) &\propto \lambda, & \lambda \rightarrow 0 \\ g(\lambda) &\propto \lambda^{-1}, & \lambda \rightarrow \infty \end{aligned} \quad (12)$$

Hence, in view of the definition of λ ,

$$\begin{aligned} \tilde{u} &\propto U^2 \frac{h}{H} L^{-1}, & \lambda \rightarrow 0 \\ \tilde{u} &\propto \frac{h}{H} L, & \lambda \rightarrow \infty \end{aligned} \quad (13)$$

Thus, whereas the residual velocity increases with the square of the tidal velocity amplitude for large topographic length scales, it becomes independent of U for smaller length scales

Observations and model studies

Very few direct measurements of residual eddies exclusively from current velocity data exist, the evidence is usually indirect in that current velocity observations of eddy-like structures are complemented by knowledge about the bottom morphology or coastal geometry, or by modelling of the flow field. This particularly applies to the spatial structure of the eddies where, for complete spatial coverage in a rather small area, a very large array of instruments would have to be used simultaneously. The former difficulty can in principle be overcome by a new method of surface current measurements using Bragg scattering of HF-radar rays, used for the observation of surface wind waves. The surface current component in the radial direction from the antenna can be determined by observing the Doppler shift in the phase velocity of the waves. By using two antennas some distance apart the complete velocity vector can be measured. Hence an area of $\sim 2,500 \text{ km}^2$ can be mapped with a high resolution in time and space, allowing residual currents to be detected by averaging the observed velocity field in time over the dominant tidal period(s)¹⁷. At present, however, its accuracy, $\sim \pm 10 \text{ cm s}^{-1}$ for an individual current speed determination, means that the method is only successful for residual currents if the associated tidal currents exceed a value of 1 m s^{-1} , say, as the residuals are usually $< 10\%$ of the tidal currents proper.

Important parameter values of residual eddies are shown in Table 1, where the crucial parameter is the residual vorticity, which can vary over some orders of magnitude, from 10^{-4} to 10^{-7} s^{-1} , generally decreasing from the coastal zone to the open sea. It never seems to be larger than the so-called planetary vorticity (the Coriolis parameter), f , which at mid-latitudes is of the order of 10^{-4} s^{-1} . This may just be coincidence for basin or headland eddies (Fig 3a, b), but can easily be explained for sand-ridge eddies (Fig 3c, d) where the Coriolis force has an important role. In that case the residual vorticity is, in fact, derived from the planetary vorticity by vortex stretching and thus is unlikely to be larger than it. Typical associated velocities lie between 1 and 10 cm s^{-1} and length scales between 3 and 30 km .

In contrast to the eddy properties inferred from current measurements in the sea, results obtained exclusively from numerical or hydraulic modelling should be interpreted with care, as the appearance of eddies in these models depends critically on the basic equations, the boundary conditions and the grid size used in a numerical model and on the scaling used in a hydraulic model.

Analytical theories tend to use highly simplified geometries such as a rectangular basin⁹, a linearly sloping bottom¹³ or a bottom consisting of a superposition of plane horizontal waves^{14, 15, 18}. Although these approximations contain the basic physics, simulating the tidal velocity field, in particular the residual field, would enable us to cope with complicated situations that cannot be handled analytically. This can be done either by direct simulation in a hydraulic scale model or by

numerically solving the nonlinear equation of motion, (6), on a grid covering the investigated area, for some suitably chosen boundary conditions.

Successful hydraulic scale modelling depends critically on whether all dominant terms in the basic equation are scaled in the same proportion (similitude). If not, the flow field of the model is likely to be distorted compared with the field in the prototype. For residual eddies, only hydraulic models for the side-wall friction mechanism (Fig 3a, b), not incorporating rotational effects, have been described for an enclosed basin^{7, 19} and for eddies produced by headlands or islands in the Seto Sea (Japan)^{6, 20}. Similitude may be expected if the Reynolds number, R_e ,

$$R_e = \frac{UL_b}{\nu} \frac{L_b}{L} \quad (14)$$

based on the ratio of vorticity advection and vorticity diffusion, is the same in model and prototype, U being the tidal velocity amplitude, L the headland or basin dimension, ν the horizontal turbulent viscosity and L_b the thickness of the frictional boundary layer. Because $L_b \propto (\nu/\sigma)^{1/2}$, where σ is the tidal frequency, this leads to similitude of

$$R_e = \frac{U}{\sigma L} = \frac{\text{tidal excursion}}{\text{basin or headland length scale}} = \lambda \quad (15)$$

Again, the ratio between tidal excursion and topographic length scale is the basic dynamical parameter. The influence of the Earth's rotation makes hydraulic simulation much more complicated for the mechanisms displayed in Fig 3c, d because here, as in the prototype, the model should rotate. No results have yet been reported.

Numerical modelling results are only known^{8, 10-12, 21, 22} for situations which belong essentially to the mechanisms of Fig 3a, b. Side-wall friction is sometimes effectively produced by introducing a bottom sloping upwards to the coast, otherwise a no-slip condition at the boundary is applied. Anyhow, decreasing velocity towards the side-walls is crucial in this case because the absence of such velocity gradients means that no vorticity is present in the velocity field, so that no residual circulation can be built up. Along the boundaries these gradients are either

Table 2 Inventory of linear tidal sand ridges according to ref. 4, together with tidal current velocities and length scale ratios λ , assuming that tides are predominantly of the semidiurnal lunar type (M_2)

supplied by viscous friction at the wall or by differential bottom friction over a bottom sloping perpendicular to the wall. Hence a no-slip condition is essential when bottom slopes near the wall are absent or weak¹⁰. This condition is often not met in numerical modelling of tidal currents. Such models therefore do not produce residual eddies by the side-wall frictional mechanism, though they may be present in the prototype. Numerically it is not difficult to keep the Coriolis acceleration in the model, but its effect on eddies produced by side-wall friction seems to be minor¹⁰.

Finally, although there are no specific results from numerical modelling of the bottom slope mechanisms (Fig 3c, d), some of the residual eddies appearing in tidal models, such as those of the North Sea^{5,23}, should be ascribed to these mechanisms. However, the grid size of these models is generally much larger than the amplitude of the tidal excursion. Thus, the shape of the weighting function shown in Fig 4b suggests that the optimum topographic length scales for production of residual circulation are not resolved by such models. Residual circulation then only appears if the bottom topography fluctuates strongly on larger length scales and, in fact, it is in such a case that the models mentioned show residual circulation. Hence much of the fine structure in the residual field may be suppressed by choosing too large a grid size. This indicates that the curves in Fig 4b imply a criterion for the set-up of a suitable grid for the numerical calculation of residual circulation¹⁴, provided the bottom topography is properly reproduced on all length scales from the grid scale upwards. Residual circulation induced by the topography can be modelled successfully if the grid size is of the order of, for example, half the tidal displacement, in which case most of the responsive scales in terms of residual velocity are covered. A much smaller grid would be more time consuming in the computation without showing much more structure in the residual velocity field. On the other hand, a larger grid size does not resolve the optimum scales where eddies may be found.

Residual eddy diffusion

Tidal currents carry water parcels only to and fro or around in a closed orbit. No water parcel can escape these predetermined pathways unless some other velocity component allows a jump from one tidal pathway to another. If these jumps occur randomly, the rate of change of the spread of an ensemble of water parcels can be used to define an effective diffusion coefficient. Normally, in a turbulent fluid, such a coefficient can be expressed in the velocity and length scales of the largest turbulent eddies present in the flow. This, of course, also applies to turbulent tidal flow regimes, where residual eddies constitute the largest scales, though it is not *a priori* clear that such eddies diffuse matter in the same way as real turbulence does. Nevertheless, it is tempting to assume that the horizontal 'residual eddy diffusion coefficient', K_e , can be expressed as

$$K_e = c\tilde{u}L \quad (16)$$

where $\tilde{u}$ and L are characteristic residual velocity and length scales. This expression has little use unless the dimensionless constant, c , can be estimated. For two areas, the Seto Inland Sea in Japan⁶ and the Dutch Wadden Sea^{16,24,25}, this could be achieved by estimating K_e from the salinity budget of the area and, independently, by estimating characteristic values for u and L from the current velocity field. For the Seto Inland Sea c appeared to be of the order of 0.4–0.5, whereas for the Dutch Wadden Sea values between 0.5 and 2.0 were obtained, compatible with diffusion coefficients of the order of 1,500 m² s⁻¹ and 400–1,500 m² s⁻¹ respectively. Thus, if equation (16) is a correct expression for K_e , c seems not to be a real constant, but must depend on (an) additional parameter(s). A guess^{16,24,26} is that these parameters are the velocity and length scale ratios λ and ν encountered previously (equations (10) and (11)). Different values of c may then be explained by these ratios (particularly λ) varying between areas. Table 1 shows that representative ranges of ν and λ are 0.1–0.2 and 0.5–3.0 respectively. The few theories^{16,24,26} which explain the depen-

dence of c on ν and λ then give a range of 0.2–2.0 for c , which is of the same order as of the values derived empirically from the salinity budget in the case studies mentioned previously.

Geomorphological implications

The shape of the coastal geometry or the bottom morphology seems to be important to any tidal residual eddy theory, but is there also a reverse effect of the residual eddies on the morphology, does any specific shape of the morphology depend on the characteristics of residual eddy circulation? Such a connection is most obvious for eddies of the type shown in Fig 3c, d. The bottom morphological structures involved are the so-called 'linear tidal sand ridges', the worldwide appearance of which has been reviewed in ref. 4. Table 2 contains information about tidal velocity amplitudes for the areas discussed in ref. 4 together with estimates of the length scale ratio λ —the fundamental parameter in residual eddy dynamics. The average length of the sand ridges is 29 ± 18 km, whereas the average tidal velocity amplitude is 0.9 ± 0.4 m s⁻¹. More relevant is the average value and spread of λ , which reads 1.9 ± 1.2 . As Fig 4b shows this is exactly the range where maximum response of residual circulation can be expected. More recent studies^{27–29} of areas not included in ref. 4 show the same order of magnitude for the length of the ridges relative to the tidal excursion amplitude. The observation that the value of λ , on average, coincides with that for maximum response of residual circulation around the ridges, suggests that during their formation the ridges somehow adjust their shape so as to maintain the largest possible residual velocities around their contours. This suggestion is intensified by the observation^{29,30} that linear sand ridges are not exactly aligned along the major axis of the tidal current ellipse, but are offset in an anticlockwise direction (8–15°) as far as ridges on the Northern Hemisphere are concerned (no observations are at hand of ridges on the Southern Hemisphere but these must show the reverse effect, clockwise inclination). As shown in Fig 3c, d

Fig 4 a, A test topography consisting of a regular series of humbs and bumps of height (+) or depth (-)h below the mean depth H . The wavelength L should be compared with the amplitude of tidal excursion l . The weighting function $g(\lambda)$ (refs 14, 15) for the Coriolis effect (solid curves) and for the bottom frictional effect (dashed curves), both for two values of the inverse bottom friction time scale r/H in equation (6), $r/H = 10^{-4}$ s⁻¹ (the highest solid and dashed curves) and $r/H = 10^{-3}$ s⁻¹ (the lowest solid and dashed curves). Note that for both vorticity production mechanisms $g(\lambda)$ has a maximum for λ in the range 1–5. The position of the maximum shifts to higher values of λ for increasing bottom friction coefficient or, equivalently, for decreasing mean water depth.

the ridges inclined anticlockwise with respect to the tidal current direction produce the largest response of residual circulation, as in that case bottom friction is reinforcing the Coriolis effect in setting-up a clockwise circulation around the bank. The geomorphological evidence shows, therefore, that both length scale and inclination of the ridges relative to the tidal current are generally such that maximum residual circulation around the ridge is produced, suggesting that this is necessary to maintain the ridge shape, which otherwise might degrade in the presence of other flattening or erosive processes. This may have some bearing on the interpretation of palaeo-environments, as these ridges are also observed in areas where a strong tidal influence no longer exists or where such ridges are buried under more recent sediments^{29,31}. For instance, the relict linear ridges found north-west of the Dogger Bank in the North Sea³¹ are thought to have been formed at ~7,000 BC when the sea level was 40–45 m lower. Whereas tidal currents are running north–south presently at the site, with a speed of $\sim 0.5 \text{ m s}^{-1}$, the orientation of the ridges implies that, at the time of their active formation, currents were predominantly running (north)east–(south)west, more or less parallel to a shoreline being formed by the northern flank of the Dogger Bank. According to the length of these relict ridges, on average 33 km (ref. 31), tidal current speeds must have been at least twice as high as they are there now.

In the case of headland eddies (Fig. 3b) it is less clear that the headland geometry itself is affected by the tidal current regime. In fact, nontidal factors principally determine the shape of the coastline. However, once the headland exists, it may produce a residual vortex pair. These vortices, in turn, collect sediment, thereby leading to the formation of sand banks^{11,12,32}. If centrifugal and Coriolis forces are both of equal importance in the eddies, sediment may accumulate asymmetrically between the eddies forming a vortex pair. The eddy showing anticlockwise circulation is preferred (on the Northern Hemisphere), because then Coriolis and centrifugal forces together with bottom friction reinforce each other in producing a convergence of bottom currents to the centre of the eddy¹¹. Thus, whereas the principal residual eddies do not depend on the existence of sand banks but on the headland geometry, imbedded within these principal eddies may be smaller ones coupled to the sand banks, which in turn are due to the sediment concentrating capacity of the principal eddies.

Finally, the geomorphological significance of the basin eddy in Fig. 3a is uncertain because it contradicts observations that in tidal channels the flood normally exceeds the ebb on the shallow sides of the channel, whereas the centre of the channel is ebb dominated^{33–36}. The sides, however, are often formed by drying tidal flats and there has been no explanation for the peculiar effects that may arise from areas uncovered by water for some time during the tidal cycle. The meandering of ebb-dominated gullies can set up a system of smaller residual cells within the overall residual pattern^{35,37,38}. It remains to be seen whether the dimensions of these cells are within the range of maximum

response for bottom morphological eddies, an observation from the Dutch Wadden Sea indicates that they may²⁴. In contrast to more open-sea areas the residual eddies suggested by ebb and flood channels in these shallow inland waters have a smaller dimension compared with the tidal excursion (a larger λ). This agrees with the result that a decrease of the bottom friction time scale, which is equivalent to a decrease in water depth, shifts the resonance peak to higher values of λ , as can be seen in Fig. 4b.

Conclusion

The existence of residual eddies in tidal areas can be largely explained by quasi two-dimensional vorticity dynamics together with a coastal geometry and/or bottom morphology providing tidal vorticity gradients. This theory does not really explain the characteristics of bottom morphological structures from the residual current velocity pattern, however. First, in residual sediment transport not only residual currents should be taken into account but also the nonlinearly generated higher harmonics in the tidal velocity field, the so-called over-tides^{12,39,40}. Yet, if sediment transport can be expressed as a function of the vertically averaged velocity, this may not be a serious flaw of quasi two-dimensional theory as over-tides appear as a by-product of residual current theory^{12–15}. Hence, a two-dimensional approach requires incorporation into the theory of a description of the interaction between (time-varying) sea-bed morphology and the tidal current regime. Such a theory might also give a first explanation of whether the bottom morphology is static or whether it may shift in space over a long time as is sometimes observed^{27,41}. However, the dimensionality of the present theories is a severe restriction. For problems of suspended sediment transport, the tidally varying vertical distribution of suspended load and velocity is important in producing residual transport, whereas for transport as bed-load the direction of the bottom current is decisive. In particular, the veering of the current direction vertically determines whether bottom currents, carrying the bulk of the sediment load, converge or diverge around any pre-existing bottom structure. Linear sand ridges, for instance, can only be maintained if there is a convergence of sediments towards the ridge crest, as is also observed indirectly by the inferred direction of bed-load transport from the properties of small sand waves on the sides of the ridge³⁰. Observational evidence on veering of tidal and residual currents near sand ridges is scarce, although the few observations we have^{42,43} support the conclusion derived from the sedimentary record³⁰. However, such observations cannot be interpreted in terms of our two-dimensional theories, and we lack the relevant three-dimensional theory.

I thank Drs J. H. Simpson and P. F. Linden, convenors of the Geophysical Fluid Dynamics Symposium at the 7th General Meeting of the European Geophysical Society, Budapest, 25–29 August 1980, who invited a review lecture on tidal residual circulation, of which the present paper is an extended version.

ARTICLES

Photoelectron spectromicroscopy

G. Beamson, H. Q. Porter & D. W. Turner

Physical Chemistry Laboratory, Oxford University, South Parks Road, Oxford OX1 3QZ, UK

Photoelectron spectroscopy is a powerful technique for studying electronic structure both of isolated molecules in the gas phase and of surfaces and adsorbed layers. Surfaces have also been imaged using photoemission microscopy. A new technique is described for combining the features of position imaging and energy analysis of the photoemitted electrons. The imaging is achieved using image projection in a divergent magnetic field to preserve the electron energy distribution.

DURING the construction of an instrument for the study of ions trapped in a high magnetic field we have explored other possibilities which this unusual arrangement of a magnetically collimated photoelectron energy analyser offers. In particular we considered imaging a surface using energy-analysed electrons. The redistribution between transverse and axial energy has a central role which depends on the divergence of the magnetic field, and this divergence produces magnification. Thus microscopy using energy selected photoelectrons is a possibility¹.

Energy analysing photoelectron microscopy

The new technique using photoelectron emission which may be seen as an extension of earlier experiments with conventional electron microscopes²⁻²², but introduces a new principle of electrostatic field-free imaging. The incident radiation (for

example, He(I) α) has a much higher energy (21.2 eV) than the work function. This enriches the image contrast by a wide range of photoelectrons from different valence levels. Energy analysis of the photoelectrons then allows spectroscopic analysis of the image.

The new technique depends on the capability of an axially symmetric divergent magnetic field to generate the enlarged image of a photoemissive object while preserving the original total energy distribution. Because the orbital moment of an electron moving in a divergent magnetic field is conserved as well as its total energy, any initially transverse energy reappears as energy of axial motion¹.

$$E = E_{\text{total}} - E_{\text{cyclotron}} \frac{B(2)}{B(1)}$$

Fig. 1 *a*, Motion of a photoelectron in a divergent magnetic field. The electron is emitted at P_1 on the flux line L_1 . Inset, projection of trajectories at the object plane which determine a maximum circle of confusion (see text). *b*, The calculated intensity of photoelectron flux across the image of a point source for $\beta = 0$. The dimension ($4R_{\text{max}}$) is determined by the largest possible orbit radius R_{max} at the object surface for a given value of magnetic field and total electron energy (see text).

Fig. 2 The magnetic projection photoelectron microscope.

where E is the final energy of forward motion, E_{total} is the total electron energy, $E_{\text{cyclotron}}$ is the amount of energy initially in cyclotron motion and $B(2)/B(1)$ is the field ratio (Fig. 1a). As no focusing elements are used, this photoelectron microscope has the maximum possible luminosity. It is a magnetic analogue of Müller's "point projection electron microscope". It is, however, capable of bringing to an image screen every photoelectron liberated with a non-zero Z -component of velocity with exactly its original energy.

The important features of the motion of an electron which originates from an object point P_1 in a high magnetic field (Fig. 1a) are, first, that the helical motion about the adjacent flux line adjusts itself to conserve the orbital moment as the flux lines diverge, so that the orbit radius is proportional to the magnification, the area magnification is $B(1)/B(2)$ and the lateral magnification is $(B(1)/B(2))^{1/2}$. Then, second and as a consequence, after a sufficiently large change of field the original photoelectron energy is concentrated in the axial motion. The first inference implies that the electrons return repeatedly to the flux line passing through the object point P_1 ; the second, that planar field retarding potential energy analysis can be performed on the total photoelectron flux at any convenient image plane in a low magnetic field region.

Lateral resolution

The resolution of such a photoelectron microscope will be limited (apart from any limitation imposed by the method used to observe the image) by deviation of an electron from the guiding field line, which is in turn determined by the original angular distribution of photoemission and the kinetic energy of the photoelectrons emerging from the surface of the object. The electrons emitted otherwise than parallel to the magnetic field execute a cyclotron orbit about the field lines and their original point of emergence is uncertain by a maximum of twice the maximum orbit diameter (D) at the surface of the object (see Fig. 1a). The cyclotron radius of an electron of total energy E_{total} emitted at an angle θ to the magnetic field direction is given by

$$R = \frac{(2mE_{\text{total}})^{1/2} \sin \theta}{eB}$$

where B is the magnetic field strength. The probability of an electron of cyclotron radius R being found within a radial distance r from the field line passing through its point of origin (Fig. 1a, inset) is given by

$$\frac{2}{\pi} \sin^{-1} \left(\frac{r}{2R} \right)$$

This probability must be weighted according to the original angular distribution of photoemission referred to the z -axis²³. The radial intensity distribution can be calculated assuming an appropriate value of β , the angular distribution parameter. Figure 1b shows the radial intensity distribution plotted for $\beta = 0$. Changes in β have little effect on the general shape of this function, which is dominated by the fact that all electrons must return repeatedly to the original field line L_1 . This function is so strongly weighted towards small r values, that we predict an ultimate effective lateral resolution (the diameter of a 'circle of confusion') of approximately $R_{\text{max}}/10$ arising from the cyclotron motion, where R_{max} is $(2mE_{\text{total}})^{1/2}/eB$.

Table 1 shows this expected lateral resolution for some useful electron energy and central (strong) magnetic field values, with the de Broglie wavelength of the free electron (λ_e) for comparison.

It is useful to compare the present method with other electron microscopies that provide chemical information. In electron probe microanalysis and scanning Auger electron microscopy, the lateral resolution is limited by the area of the probe electron beam at the surface and is typically 0.3–0.5 μm using a thermal electron source. In scanning Auger microscopy with a cold-cathode field emitting source, the lateral resolution is limited²⁴ to ~30 nm and further improvement is prevented by electron scattering in the sample.

Thus from Table 1, in the present instrument, with a field strength of ~8 T, a useful microscopic performance is obtainable. For example, with 5-eV electrons, we could expect 0.1 μm resolution and in the highest readily attainable superconducting solenoid field, of ~16 T, performance should be at least comparable in lateral resolution to that of scanning Auger electron microscopy when lowest energy ($\approx kT$) photoelectrons are selected using samples at ordinary temperatures.

Depth resolution

Depth resolution (as opposed to lateral resolution) is sometimes referred to as depth of information and is related to the escape depth. (This should not be confused with depth of field, which is an instrumental property of a lens system and does not concern us because the present instrument is non-focusing; the field depth is limited only by the range of illumination of the object.) Thus a depth of information of d nm indicates that the final image is formed by photoelectrons that originate within a distance d of the surface.

The penetration depth of UV radiation is of the order of 1 μm but the electron escape depth is of the order of 0.5–20 nm. The precise value depends on the angle of exit and energy of the

Table 1 Lateral resolution of the magnetic projection photoelectron microscope for various electron energies and central magnetic fields

Electron energy (eV)	Expected lateral resolution (μm) for central magnetic fields (T)				de Broglie wavelength (μm)
	1	4	8	16	
500	8.0	2.0	1.0	0.5	5×10^{-5}
5	0.8	0.2	0.1	0.05	5×10^{-4}
0.05	0.08	0.02	0.01	5×10^{-3}	5×10^{-3}

photoelectron²⁵. The information depth is between 1 and 20 layers. The depth resolution in photoelectron microscopy is thus comparable with Auger electron microscopy and much higher than scanning electron microscopy. This high depth resolution means that in the study of metal surfaces for example, only the top few layers of atoms will contribute to the image. For biological surfaces, a depth of information of a few nanometres would permit a plasma membrane to be imaged while discriminating against the cytoplasm (see, for example, ref. 26). Depth of information is a function of incident light wavelength, angle of incidence and of any surface monolayers. Use of monolayer coating with a judicious choice of incident light parameters might further reduce the depth of information.

Energy resolution

By observing changes in the image as a function of the secondary electron energy distribution, scanning electron microscopy can, for example, discriminate between features whose secondary electron yield functions differ by as little as 0.5 eV. Con-

ventional UV photoelectron spectroscopy, however, has afforded energy discrimination as small as a few meV when isolated molecules are photoionized in the vapour phase²⁷ and, although band broadening effects in solids generally make the extremely high resolution of such experiments unnecessary, the possibilities for mapping a surface with such high energy resolution are extremely attractive. For example, sharp peaks (< 0.1 eV) have been seen in angle-resolved photoelectron spectra from surface states in copper²⁸ and gold²⁹. Some semiconductors and surface layers of weakly adsorbed species also exhibit narrow bands. Using the present instrument as a retarding potential analyser for gases gives an energy resolution of 20 meV—this may be capable of further improvement.

The present instrument

Figure 2 illustrates the present instrument. The divergent magnetic field is produced by a 'split-pair' superconducting solenoid whose central field can vary from 0 to 7.7 T. A gold-coated cubic electrode structure at the centre of the solenoid establishes a unipotential region, with various apertures for a 1-mm diameter collimated photon beam (initially of 21.2 eV photons from a He(I) d.c. discharge lamp), a sample probe, and for the emergent photoelectrons. The probe bearing the solid sample is mounted on the arm of a vacuum manipulator and can be translated and rotated.

Outside the solenoid, the magnetic field strength along the instrument axis is controlled using a magnetic shielding cage within the electron flight tube, and a system of axial and transverse correction coils outside the flight tube.

The magnetic shielding cage is an assembly of 24 gold-coated silver steel rods which reduce the magnetic field produced by the

Fig. 3 He(I) photoelectron micrographs of some test samples mounted on a hypodermic syringe needle. Brass wire inserted in the small hole (a). The edge of an acid-etched copper fragment (b), grains of pollen (c), a flake of oriented graphite (two orientations: d, e). Dark lines seen in these micrographs are shadows of the retarding grid wires (see text).

Fig. 4 He(I) photoelectron micrographs of a fragment of crystal-line chromium trisacetyl acetate attached to a stainless steel needle using electrons of energy greater than: a, 14 eV; b, 13 eV; c, 12 eV; d, 11 eV; e, 10 eV; f, 0 eV. Magnetic field strength 5 T. Thickness of the crystal $\sim 100 \mu\text{m}$.

superconducting solenoid within the cylinder. This, together with the external axial coils, is designed to establish a field which falls from a value of the order of 0.01 T at the nearest end to ~ 0.001 T at the furthest when the main field is at its maximum value. This large field reduction provides a magnification of the order of 100 and electron energy resolution is limited only by surface micropotentials (see Fig. 2 of ref. 1). With the present

arrangement, the argon photoelectron spectrum obtained in integral mode shows an energy resolution of ~ 20 meV. The resolving power of the retarding analyser is approximately constant in the 1–10 eV kinetic energy range.

A secondary function of the gold-plated silver steel rods is to establish a uniform transverse electrostatic field as an alternative way of energy analysis. Mounted at the front end of the shielding cage is a gold-coated tungsten wire grid with 95% transparency which, together with a system of gold-coated stainless steel rings, establishes a planar retarding field energy analyser. At the outer end of the shielding cage is the electron detection and imaging system. This consists of a 2-inch diameter microchannel plate (25- μm channel spacing) and low energy phosphor screen.

The lateral resolution of object detail is limited to $\sim 2 \mu\text{m}$ mainly by the coarseness of the 'home-made' phosphor screen and vibrations at the object. Ultimately, the limit will be imposed by the channel plate structure and the finest channel plate structure available (12 μm) would correspond to a lateral resolution of the object of 0.12 μm when $B(1)/B(2)$ is 10^4 . The photographs in Figs 3–7 are degraded by marked 'blooming' in the TV image close to features having high intensity. Both of these defects should be removed by using a charge-coupled electron image sensor.

The He(I) photoelectron count rate at the phosphor screen is typically 50,000 c.p.s. from argon at 2×10^{-5} torr. With a solid sample, the electron flux is too large for electron counting. The image on the phosphor screen is observed by a television camera and can be photographed directly from a video monitor. Alternatively, the camera output can be digitized and stored in a micro-computer, either as the whole picture frame or just one line or section of a line. In the latter case, the computer is used to advance the retarding potential on the analyser as successive frames are scanned and so to build up an array of spectra along a particular picture line segment. This array of integral spectra can be processed to yield the more familiar form of differential photoelectron spectra (see, for example, Fig. 7).

The vacuum chamber of the instrument is pumped by a 5-inch diffusion pump through a water-cooled baffle and liquid nitrogen trap. Thus a background pressure of 10^{-7} torr is readily achieved when the helium lamp is operating.

Although the present instrument has no vacuum lock for sample changing nor a separate argon ion gun for surface etching, *in-situ* cleaning is straightforward, with the strong magnetic field playing an important part. When argon is admitted to the working region to a total pressure of $\sim 100 \mu\text{m}$, a

Fig. 5 a, Helium (I) photoelectron micrograph of pollen grains attached to a syringe needle. b, c, Digitally accumulated pictures of the same subject using electrons of energy greater than 5 eV (b) and 13.5 eV (c).

Penning-type glow discharge is established with ~ 400 V between the sample support and the surrounding cage. A current of ~ 0.1 mA for a few minutes causes rapid changes in the images of both metallic and plant material surfaces.

Examples

As a preliminary demonstration, a few fragments of mineral and biological origin were attached to the top of a hypodermic syringe needle placed on the manipulator. Figures 3–7 show images obtained by photographing the normal TV image on a monitor screen together with their electron energy distributions along a chosen TV raster line. The direction of illumination by the He(I) beam is indicated.

Figure 3 shows a haphazard collection of objects imaged using electrons of all energies, that is the retarding potential of the analyser was set to zero. The images are (a–e) of a 250 μm brass wire, the edge of an acid-etched annealed copper foil fragment, some pollen grains and two views of a flake of 'oriented graphite' (UCAR) stuck tangentially to the needle surface.

Images of a microcrystal of chromium (III) triacetylacetonate ($\text{Cr}(\text{Acac})_3$) some 100 μm thick obtained using energy analysed electrons are shown in Fig. 4. The image of the supporting surface (stainless steel) could be completely suppressed by observing only high energy electrons (> 11 eV). Much more significant is the variation of relative brightness of the different crystal faces at different voltages. One face in particular (the right-hand edge in Fig. 4), which is both illuminated and observed at near grazing incidence, remains visible in photoelectrons of energy 17 eV. At low electron energy the end of the crystal facing the beam is the strongest emitter (this is not clearly shown in the present series of photographs because the vidicon was overloaded).

Fragments of plant material (pollen grains, cellular fragments and fibres) showed similar behaviour when observed immediately after sample insertion and initial evacuation, or after brief argon ion bombardment. But the maximum kinetic energy for photoelectrons was generally lower (~ 14 eV) although higher energy photoelectrons could be observed from selected areas with carefully controlled ion-cleaning. Figure 5a shows the > 10 eV photoelectron image of a pair of pollen grains (diameter ~ 50 μm) on the stainless steel surface together with computer-stored images obtained using > 5 eV (Fig. 5b) and > 13.5 eV (Fig. 5c), photoelectrons. The pollen grains (of *Echinopsis eyriesii*) have slightly dimpled spherical surfaces but the images show a marked spatial dependence of the energy distribution.

Fig. 6 a, b, c, He(I) photoelectron micrographs of a fragment of poppy anther using: a, all electrons; b, electrons of energy > 8 eV and c, electrons of energy > 11 eV. Magnetic field strength, 4 T. d, Photoelectron energy spectra (16 eV energy scale) along the raster line by arrows.

In a more complicated plant fragment (of poppy anther), an interesting variation of electron energy distribution along a selected line can be discerned (Fig. 6d) related to the intensity distribution in the different images obtained as the retarding potential varies (Fig. 6a, b, c).

Figure 7 shows the change in photoelectron emission from an acid-etched copper surface as it is cleaned by ion bombardment. Figure 7a is an all-photoelectron micrograph of the copper surface before cleaning. Figure 7b–d shows the changes which occur in the electron energy distribution along the arrowed line in Fig. 7a as the surface becomes cleaner. Figure 7b shows the uncleaned surface. Figure 7c, d shows the progressive changes after Ar^+ bombardment. A low-electron energy band is progressively lost. The final observed spectra do not have the appearance of conventional photoelectron spectra of copper surfaces for several reasons. First, although the annealing and acid etching did afford a surface topography showing the presence of different crystallites, the exposed faces were ill-defined crystallographically. Second, the distribution is not angle resolved. In effect we have integrated the spectra over the emitting hemisphere. This is, of course, a feature of the magnetic projection. All emitted photoelectrons are collected. Third, in this preliminary study the surface is not completely clean even after ion bombardment, in particular the Fermi edge is still suppressed.

The bright line on the left of Fig. 7a is photoemission from the epoxy resin used to mount the copper sample, together with its shadow. The difference in contrast arising from the different photoelectron energy distribution is quite striking at certain analyser voltages.

Conclusions

We have demonstrated that photoelectron images of microscopic surface structure can be obtained using energy-analysed electrons. The He(I) resonance line was used for the demonstration because it is easy to generate and has been widely used in the study of surface valence and photoemission. For element mapping, however, other resonance lines could be used. For core electrons, in particular, soft X-ray lines and synchrotron radiation may have advantages where it is possible to match the photon energy to a suitable shell or sub-shell ionization energy of the required element. This technique thus has the unique ability of producing either a molecular or atomic map of the surface depending on the photon energy. Scanning Auger

Fig. 7 *a*, He(I) photoelectron micrograph of an acid-etched copper surface before ion bombardment. Magnetic field strength, 7 T. *b*, *c*, *d*, The changes in photoelectron energy spectra along the raster line marked by arrows, as the surface is progressively cleaned by argon ion bombardment.

microscopy, on the other hand, provides only an atomic or elemental map of the surface. By using a photon energy only slightly in excess of the ionization energy both lateral resolution and sensitivity will be at the optimum. When the sample is irradiated near grazing incidence, photoemission is concentrated in the first atom layer and depth resolution is then at its optimum.

A most important advantage may, however, be derived from the much less destructive nature of the photoemission process combined with the high electron collecting efficiency.

To obtain good lateral resolution in Auger microscopy a current density of 10 A cm^{-2} is required²⁴. In such irradiation electron trapping, charging and secondary electron emission are important and the following electron-induced artefacts can be observed: migration of surface ions, decomposition, electron-induced desorption and diffusion induced by local Joule heating. The power dissipated in the sample by the He(I) discharge lamp is estimated to be less than that in the Auger electron micro-

scope by a factor of 1,000 or more. The advantage may be considerably larger, when the reduction in chemical damage associated with photons compared with electrons is taken into account.

The use of a very strong magnetic field, though primarily instrumental in intent, also has important possibilities for the study of energy bands and spin polarization in magnetic materials. This, when combined with the imaging property, may be particularly valuable in materials science in the study of magnetic domains. Photoemission from a ferromagnetic material in which the domains have been aligned by an external 0.05 T field is known to lead to spin-polarized photoelectrons³⁰.

Identification and nucleotide sequence of a diversity DNA segment (D) of immunoglobulin heavy-chain genes

Hitoshi Sakano, Yoshikazu Kurosawa, Martin Weigert & Susumu Tonegawa

Basel Institute for Immunology, 487 Grenzacherstrasse, Postfach, 4005 Basel 5, Switzerland

A putative diversity segment of immunoglobulin heavy-chain genes (D segment) has been identified 700 base pairs 5' to J_H DNA on the germ-line genome of the mouse. This 10-base pair D segment is flanked by two sets of sequences related to

CACTGTG and GGTTTTGT
GTGACAC and CCAAAAACA

which are possible recognition sites for a recombinase. The spacer separating the heptamer and the nonamer is 12 base pairs long on both sides of the D segment. As the spacer separating the two signal sequences in V_H DNAs and J_H DNAs is 23 ± 1 base pairs long, the two recombinations required for creation of a complete immunoglobulin V_H gene, a V_H -D joining and a D- J_H joining, follow a 12/23-base pair spacer rule. Allelic exclusion is discussed with respect to D segments.

It is well established that complete immunoglobulin variable region genes (V genes) are generated by somatic DNA recombination(s) during the development of B-lymphocyte cells¹⁻¹⁵. In the light-chain genes of the mouse, in both λ - and κ -types, the last 13 COOH-terminal residues of the variable region are encoded by a separate DNA segment called J DNA (J for joining) in the germ-line genome^{4,7,9,10}. Coding information for the rest of the V region is contained in an embryonic V DNA segment^{3,6,7,9,10}. Accordingly, somatic recombination occurs between the 3' end of the V DNA and the 5' end of the J DNA to generate a complete light-chain V gene^{4,6,8}. The $J\lambda_1$ (ref. 6) and five $J\kappa$ DNAs^{9,10} carry two blocks of sequences, one a palindromic heptamer, CACTGTG, and the other a nonamer, GGTTTTGT, highly conserved in the 5'-noncoding regions. These conserved sequences are invertedly repeated in the 3'-noncoding regions of all embryonic $V\lambda$ and $V\kappa$ DNAs sequenced to date^{3,6,7,9,10}. Another striking feature around the recombination site is that the spacer between the heptamer and the nonamer^{12,13} in all V and J DNAs is 12 ± 1 or 23 ± 1 base pairs long. In addition, recombination seems to occur only between a V DNA with the shorter (12-base pair) spacer and a J DNA with the longer (23-base pair) spacer or vice versa (12/23-base pair spacer rule). Based on these observations

Early *et al.*¹² and Sakano *et al.*¹³ predicted that the same or a similar enzyme mediates the recombinations in both λ - and κ -light-chain genes and that the recombinase consists of two functionally distinct units, one recognizing the heptamer and the nonamer separated by the shorter (12-base pair) spacer and the other recognizing the same signal sequences separated by the longer (23-base pair) spacer.

In contrast to the light-chain genes, heavy-chain J DNAs (J_H) do not seem to associate directly with the heavy-chain V DNAs (V_H). In the case of the $\gamma 2b$ heavy-chain gene expressed in myeloma MOPC141, the 14-residue peptide comprising the third hypervariable region (HV3) beginning with Val (residue 98) and ending with Thr (residue 111) is encoded neither in the germ-line V DNA nor in the J DNA¹³. A similar observation has been made independently in an α heavy-chain gene¹². Therefore, it is generally believed that the HV3 region of a heavy chain is encoded by a separate DNA segment, D (D segment for diversity¹⁶), and that two recombination events, V_H -D and D- J_H joinings, are necessary to form a complete heavy-chain V gene. All germ-line V_H DNAs and J_H DNAs sequenced so far have the conserved heptamer and nonamer separated by the longer spacer. It has therefore been predicted^{12,13} that germ-line D segments must contain the same recognition sequences on each side of the coding segment and their spacers must both be short ones, so that the 12/23-base pair spacer rule is adhered to. However, no germ-line D sequence has been reported to date and the predictions outlined above still need to be verified. It was previously observed that the DNA sequences are often rearranged in the J_H cluster in some cloned T-cell lines^{17,18}, as well as in pre-B-cell lines^{18,19}. By the Southern hybridization method using a J_H cluster probe, we observed that DNA rearrangements within the J_H cluster region are not restricted to one allelic chromosome in most of the myelomas. One intriguing possibility was that some of these rearrangements were abortive, representing recombination between a D segment and a J_H segment producing an incompletely rearranged D- J_H structure. We therefore cloned some of the genomic DNA fragments containing the rearranged J_H -cluster sequence from myelomas and characterized the cloned DNA fragments. These studies led to an identification of a potential germ-line D DNA segment, which is reported here. This potential D DNA segment is flanked by the two pairs of conserved sequences in inverted orientations, and the spacers separating the two signal sequences are 12 base pairs long for both.

Fig. 1 Southern blot analysis of mouse embryo and myeloma DNAs. Mouse DNAs were digested with *Eco*RI, separated in 0.8% agarose gels and blotted to nitrocellulose filters according to the method of Southern²⁰. Filters were then incubated with the nick-translated J_H probe (1.1-kilobase *Sac*I-*Eco*RI fragment, see ref. 11), essentially as described by Wahl *et al.*³⁹. *Hind*III fragments of phage λ DNA were used as size markers (in kilobases, kb). For the cloning of a 5.2-kilobase Q52 fragment hybridizable with the J_H probe, *Eco*RI digest of the myeloma DNA was fractionated in a 0.8% agarose gel and DNA from the J_H probe-positive fraction was eluted as described previously⁴⁰. Recombinant phages containing the mouse DNA were screened by *in situ* plaque hybridization⁴¹ with the J_H probe.

Fig. 2 A, Electron micrograph (a) and schematic interpretation (b) of a heteroduplex molecule formed between two *Eco*RI inserts, one from clone ME184-8 (embryonic J) and the other from clone Q52J (rearranged J from myeloma QUPC52). Procedures used for the heteroduplex formation have been described previously⁴. Clone ME184-8 was prepared by Richard Maki and contains, in a phage λ WES vector, the 6.4-kilobase *Eco*RI embryo DNA fragment carrying the four J_H DNA segments whose sequences were determined previously¹³ using another DNA clone referred to as MEP203 (ref. 11). Numbers indicate lengths of various parts of the heteroduplex in kilobases. B, Restriction enzyme cleavage maps of the J-containing *Eco*RI fragments. a, 5.2-kilobase insert from the myeloma clone Q52J; b, 6.4-kilobase insert from the embryonic clone ME184-8. The broken line (Δ) in Ba represents a deletion in the myeloma clone; the bars in Bb indicate coding regions. The positions of four J_H segments have been determined by R-loop mapping and DNA sequencing^{11,13}. The D segment is identified in the present study by DNA sequencing of the 5' flanking region of J_{H1} . Strategy of the sequencing is shown in Bc. kbp, Kilobase pairs; bp, base pairs. The previously published *Bam*HI sites¹³ have been corrected.

Frequent rearrangements of the J_H region sequences in myelomas

We analysed *Eco*RI digests of total DNA from 18 different BALB/c myelomas by the Southern gel blotting method²⁰ using a J_H probe (Fig. 1). The embryo DNA gave a band of 6.4 kilobases as expected from previous studies¹¹. All but three (MOPC511, MOPC21 and MOPC321) myelomas gave one, two or three bands that are all different from the embryo band. MOPC511 and MOPC21 each gave two bands, one of which is indistinguishable from the embryo band. MOPC321 gave no band. This myeloma synthesizes no heavy chain and presumably lacks part of the heavy-chain gene sequences in question. In some myelomas a very faint band can be seen at the position of the embryo band, probably due to contamination of non-myeloma cells in the solid tumours from which the DNA was prepared. The variability in the number of bands among various myelomas and in the intensity of bands within a myeloma most probably reflects the fact that myelomas are usually not diploid²¹.

We assume that one rearranged band in each myeloma represents the V_H -D- J_H joining required for the formation of a complete heavy-chain gene active in that myeloma. Although the nature of the additional rearrangements observed in many myelomas is unknown, the results show that sequence rearrangements are very frequent in the vicinity of the J_H cluster in all copies of chromosome 12, on which the heavy-chain genes reside²².

DNA deletion on an abortively-rearranged J_H fragment in myeloma QUPC52

We chose the 5.2-kilobase QUPC52 (Q52) fragment for further analysis and cloned it in the phage vector λ WES (ref. 23). The cloned *Eco*RI fragment was analysed by heteroduplex formation using a germ-line J_H fragment (clone ME184-8) cloned from the *Eco*RI digest of mouse embryo DNA. As shown in Fig. 2A, the 5.2-kilobase myeloma fragment carries a 1.1-kilobase deletion, which lies 3.0–4.1 kilobases from the 5' end of the embryonic J_H fragment. By superimposing the heteroduplex map on the restriction enzyme map of the embryonic clone, we could locate the right end of the deletion near the J_{H2} DNA and the left end about 0.7 kilobases 5' to the J_{H1} DNA (Fig. 2B).

D-like segment is attached to J_H DNA on the abortive clone

To analyse the structure of the DNA segment joined to the J_H region, we purified a 600-base pair *Bgl*II-*Bam*HI fragment (see Fig. 2Ba) from the myeloma clone and determined the nucleotide sequence. Figure 3b shows the nucleotide sequence of a 110-base pair *Hinf*I-*Hinf*I fragment containing the deletion. As expected, we found the J_{H2} sequence in the sequenced region. By comparing this myeloma sequence with the germ-line J_{H2} sequence (Fig. 3b, c) we found that the J_{H2} sequence starts with the third nucleotide of the Asp codon at position 101 (number-

Fig. 3 Nucleotide sequence of the D-J structure in a myeloma clone, Q52J (b), and its germ-line sequences, J_{H2} (c) and D_{Q52} (a). For the sequencing of b, a 110-base pair *Hinf*I-*Hinf*I fragment containing a deletion was purified from a 600-base pair *Bgl*II-*Bam*HI fragment (see Fig. 1Ba), both ends labelled with [α -³²P]-nucleoside triphosphates, and the strand separated and sequenced in both directions according to the procedures described previously²². The embryonic J_{H2} sequence (c) was taken from ref. 13. The embryonic D_{Q52} region (a) was sequenced according to the strategy shown in Fig. 2Bc. Two blocks of conserved sequences,

GGTTTTTGT and CACTGTG
CCAAAACA and GTGACAC

or their related sequences are boxed. Numbers indicate lengths of spacers separating the two conserved sequences in base pairs. Sequences in a and c contributing the coding region in b are underlined. The corresponding sequences in b are also underlined. Note that tetranucleotide AAGG in b between the two boundaries of D_{Q52} and J_{H2} is not accounted for by either germ-line sequence. Vertical lines indicate possible recombination sites with D_{Q52} and J_{H2} . Encoded amino acid sequences are in italics.

or their related sequences are boxed. Numbers indicate the lengths of the spacer separating the two conserved sequences in nucleotide bases.

ing is after Kabat *et al.*²⁴). The myeloma sequence of the 3'-flanking region of J_{H2} is identical to the embryonic sequence (data not shown). Thus, the right end of deletion was identified between the second and third nucleotides in the Asp codon (Fig. 3b). We then examined the sequence preceding the J_{H2} on the myeloma clone. As shown in Fig. 3b, a palindromic heptamer, CACAGTG, and a T-rich sequence, GGTTTTGAC, closely related to the nonamer GGTTTTGT, are present 14 and 26 base pairs, respectively, 5' to the recombination site. The spacer separating the heptamer and the nonamer is 12 base pairs long. These structural features of the DNA attached to the Q52 J_{H2} sequence fit the predictions made for the D segments. We could not find any V-like sequence on the 5' side of the recombination site, and this would have been easy to detect, as the sequence at the end of V DNA coding for residues 90-94 is highly conserved²¹.

Identification of a germ-line D segment

If the rearrangement on the Q52 clone represents the deletion between a D segment and a J_H segment, the germ-line D sequence must be on the 6.4-kilobase embryonic J_H fragment. As shown in Fig. 2, the left end of the deletion on the Q52 clone has been mapped 0.7 kilobases 5' to the J_{H1} DNA on the germ-line clone. We therefore extensively sequenced the 5'-flanking region of the J_H DNA cluster on the embryonic clone. Figure 4 shows the complete nucleotide sequence of the 1-kilobase region upstream from J_{H1} DNA. As predicted, about 700 base pairs 5' to the J_{H1} we identified the same sequence as found on the 5' side of Q52 J_{H2} DNA. In this germ-line sequence another set of the palindromic heptamer and the T-rich nonamer are invertedly repeated on the 3' side (Figs 4 and 3a). Again the spacer separating the heptamer and the nonamer is 12 base pairs. Accordingly, this germ-line sequence has the structure predicted for the germ-line D segment. In the D-like segment identified here, a 10-base pair DNA stretch is flanked by two palindromic heptamers.

CCAAAAC TG TGTTTTGG

12 base pairs outside. This 10-base pair segment can code for three amino acid residues, Gln-Leu-Gly, Asn-Trp-Asp or Thr-Gly-Thr. Although no published mouse HV3 sequence cor-

responds to these hypothetical peptide sequences, we tentatively refer to this potential D segment as D_{O52}.

The tetranucleotides, AAGG, adjacent to the recombination site on the Q52 J_{H2} DNA cannot be explained by either the germ-line J_{H2} or the D_{Q52} sequence (Fig. 3), and at present the origin of this sequence is unknown. We looked for another germ-line D segment encoding the tetramer between the D_{Q52} and J_{H1} sequences and found none (Fig. 4). As shown in Fig. 3a, the coding sequence in the embryonic D_{Q52} segment is followed by pentanucleotides CACGG. If we assume one nucleotide deletion and one nucleotide substitution in this pentamer, the tetramer AAGG could be generated. These events might have occurred somatically on recombination (see the accompanying article¹⁷ for more discussion on this point).

In the hope of finding another D segment, we extensively sequenced the 1.3-kilobase segment 5' to D_{Q52} according to the strategy shown in Fig. 2Bc (sequence not shown). However, detection of another D or D-like sequence was unsuccessful: therefore, germ-line D segments do not seem to be as tightly clustered as are J_H DNAs.

Generality of the 12/23-base pair spacer rule

The present study extended the 12/23-base pair spacer rule^{12,13} to germ-line D segments. It thus seems that all recombinations leading to formation of a complete V gene are mediated by the same or similar enzymes. These enzymes are thought to contain two DNA-binding proteins, one for a DNA segment carrying the heptamer and nonamer separated by a short (12-base pair) spacer and the other for a DNA segment having essentially the same short sequences separated by a long (23-base pair) spacer^{12,13}. As the two pairs of the putative recognition sequences are in an inverted orientation relative to the corresponding coding DNA segments, they could form a transient intermediary duplex if it is stabilized by the recombinase^{9,13}.

D-J_H joining accompanies a deletion

It seems to be a general rule that sequence rearrangement involving immunoglobulin genes accompanies a deletion of the DNA sequence which separates a pair of joining DNA segments on a germ-line genome. Experimental evidence for this rule was first obtained for V-J joining of the λ_1 -type light-chain gene⁹, and was confirmed in a subsequent experiment²⁵ in the κ -type gene. There is also evidence that deletions accompany heavy-chain joining^{18,26}. Furthermore, a number of groups reported results which strongly suggest that the same rule applies to the 'switch recombination' of heavy-chain genes^{27-30,44}. All the evidence is based on hybridization analysis of mouse DNA using

an appropriate probe. The heteroduplex molecule, formed between the embryonic J_H clone and the Q52 J_H clone, provides the most direct evidence for the involvement of deletion in D- J_H joining. As the size of the cloned DNA fragments corresponds well to those of the fragments detected by Southern gel blotting analysis, the deletion cannot be attributed to cloning artefacts (see Fig. 1 for clone Q52 J_H).

D- J_H joining and allelic exclusion

Unlike all previous autosomal gene studies, only the gene on one of the two homologous chromosomes is active in a given cell for immunoglobulin chains³¹⁻³³. This 'allelic exclusion' is manifested in several ways for light chains. A common form is that one copy of the chromosome contains a rearranged, complete gene, and the other retains the germ-line configuration⁴. Alternatively, both alleles are rearranged, but one abortively in several different forms (refs 5, 18, 33-36, 45-48 and P. Kennedy and S.T., unpublished). At the heavy-chain locus, rearrangements on both copies of the chromosome seem to be very common (Fig. 1), and lack of rearrangement as observed in light chains does not seem to be a common form of allelic exclusion. The demonstration that the heavy-chain locus includes D DNA segments suggests a unique way in which this locus can be abortively rearranged. As shown here for myeloma QUPC52,

the unexpressed chromosome contains a D-J segment. Although allelic exclusion at the heavy-chain locus could be manifested by other forms of abortive rearrangement observed in the light-chain loci, the existence of D segments may provide additional forms. One might imagine that in addition to D-J joining V-D joining can occur.

The analysis of myeloma DNA indicates that rearrangement in the vicinity of J DNA segments is much more frequent in heavy-chain genes than in light-chain genes. This distinction also applies to normal B cells: little, if any J_H was observed in the germ-line configuration³⁷, whereas unrearranged J_K is observed in significant amounts³⁸. The reason for this difference is not clear. However, it is reasonable to assume that the frequency of joining of two separate DNA segments increases as the number of segments increases and/or as the distance between them decreases. If there are many D segments (see the accompanying article¹⁷) and if they are close to J segments as D_{Q52} is, D-J joining could account for more frequent abortive rearrangement in the heavy-chain locus.

We thank Lisa Sultzman, Lena Angman, Patricia Riegert and André Trauneker for technical assistance, Richard Maki and William Roeder for reading the manuscript, and Michael Potter for myelomas. The Basel Institute for Immunology was founded and is supported by F. Hoffmann-La Roche & Co.

Identification of D segments of immunoglobulin heavy-chain genes and their rearrangement in T lymphocytes

Yoshikazu Kurosawa, Harald von Boehmer, Werner Haas, Hitoshi Sakano, André Trauneker & Susumu Tonegawa

Basel Institute for Immunology, 487 Grenzacherstrasse, Postfach, 4005 Basel 5, Switzerland

The finding that the diversity (D) and joining (J_H) but not the variable (V_H) DNA segments of mouse immunoglobulin heavy-chain genes are joined in the DNA of some cloned cytolytic T cells, led to identification and sequencing of three different D DNA segments. Two segments identified on the embryo DNA carry on both the 5' and 3' sides two sets of characteristic sequences separated by a 12-base pair spacer, which have been implicated as recognition signals for a recombinase. The third segment, identified in a form joined with a J_H DNA segment in a T cell, carries the recognition signal on the 5' side. These results support the 12/23-base pair model for somatic generation of immunoglobulin V genes, and rule out the possibility that the cytolytic T cells use assembled V_H , D and J_H sequences to encode their antigen receptors.

THE variable region of an immunoglobulin chain is encoded in multiple DNA segments scattered along a chromosome of a

germ-line genome¹⁻¹⁰. These DNA segments are assembled into a continuous stretch with concomitant deletion of the spacer

sequences during differentiation of B lymphocytes. The somatic rearrangement of DNA sequences is considered to have key roles in both somatic amplification of antibody diversity and determination of the specificity of lymphocyte clones. In mouse light chains of both λ and κ types, two DNA segments, V and J, are separate in the germ-line genome and are joined in the lymphocytes which express these DNA segments¹⁻⁵. The V and J segments code for about 95 residues at the NH₂-terminal and about 13 residues at the CO₂H-terminal ends of the V region, respectively^{1,3-5}. In contrast, DNA sequencing analysis of heavy-chain genes suggests that the V_H region is encoded by three DNA segments referred to as V_H, D and J_H, and somatic joining of the three DNA segments is necessary to generate a complete heavy-chain V gene⁶⁻⁸. The D DNA segment encodes the third hypervariable region, which determines in part the shape and size of the antigen-combining site^{11,12}.

The abovementioned sequence rearrangement of immunoglobulin genes should occur during the development of B lymphocytes before the appearance of the first detectable immunoglobulins. Does an analogous or similar rearrangement occur in the precursors of T lymphocytes, which share a common stem cell with B lymphocytes? This question is particularly important because of the possible use of the immunoglobulin V gene pool by T cells for coding their antigen-specific receptors¹³⁻¹⁶. One approach to this question is to analyse DNA of cloned T cells by the Southern gel blotting procedure using a J DNA sequence as the hybridization probe. A V-J or V-D-J joining will be monitored by a difference in the size of DNA fragments detected in embryo (or kidney) and T-cell DNA. We have therefore applied this technique to several cloned cytolytic T cells, and show here that sequence rearrangements frequently occur in T cells in the vicinity of the J_H sequences. Similar findings have been reported by two other groups with T-lymphoma lines¹⁷ and cytolytic T-cell lines¹⁸. However, our further analysis of two T-cell clones by recombinant DNA techniques demonstrates that the rearrangements observed in these T-cell clones are D-J joinings rather than V-D-J joinings. This led to the identification of two D DNA segments on the germ-line genome. One of the three D DNA segments described here was found to be identical to the D segment that was independently identified in our laboratory during the parallel analysis of an abortively rearranged sequence observed in the myeloma QUPC-52 (ref. 19).

T-cell DNA sequence is frequently rearranged in the vicinity of the J_H cluster

We have previously identified a cluster of four J_H DNA segments⁷ on a 6.4-kilobase *Eco*RI fragment cloned from BALB/c embryos (clone MEP203)⁶. A 1.1-kilobase *Sac*I-*Eco*RI fragment derived from the 3' end (relative to orientation of transcription) of this fragment (a J_H probe) would detect, when used as a hybridization probe on Southern blots of cellular DNA digested with *Eco*RI, sequence rearrangements that have occurred within the 6.4 kilobase *Eco*RI fragment. The results of various cytolytic T-cell clones and three thymomas are shown in Fig. 1a. The cytolytic T-cell clones, except B6.1, were confirmed for their functional activity before extraction of DNA. The embryo or kidney DNAs of five different mouse strains—BALB/c, C3H, C57BL/6, AKR and DBA—all gave the expected fragment of 6.4 kilobases previously identified. The DNA of three cytolytic T-cell clones—DAS 1, D.FL.2, D.FL.13—and two thymomas—BW 5147 and T5—each gave a single band indistinguishable from that of embryos or kidneys, suggesting that no gross sequence rearrangement has occurred in these cells within the 6.4-kilobase *Eco*RI fragment. [The faint bands observed above the 6.4-kilobase band in D.FL.2 and D.FL.13 DNA are due to incomplete digestion as demonstrated by separate experiments (data not shown).] In contrast, DNA of six cytolytic T cells—C.SP.2, C.FL.1, B6.1, D.FL.1, D.FL.12 and D.FL.16—gave one additional band of 5.5, 5.3 or 4.0

Three germ-line D sequences identified in the present study are compared with the D region sequences of the eight complete V_H genes present in the indicated myelomas. For D_{SP2.2} and D_{Q52} the sequences between the palindromic heptamers are shown. The D_{SP2.1} has been identified only in a form joined with the J_{H3} segment and therefore its exact 3' boundary is unknown. For S107 (ref. 8), M603 (ref. 8), M167 (ref. 8), MC101 (ref. 27) and M141 (ref. 7) the DNA sequences of both the complete (rearranged) and the embryonic (unrearranged) V_H genes are known. These sequences and the embryonic J_H sequences⁷ were used to deduce the 5' and the 3' boundaries of these D regions. For MPC11 (ref. 28), M173-II (H.S. and Y.K., unpublished) and H76 (ref. 9), only the DNA sequences of the complete V_H genes are known and therefore the 5' boundaries are ambiguous. The 3' boundaries were deduced as above. All sequences are aligned for the maximal homology. The D regions of S107 and M603 contain a 13-mer (underlined) which is a perfect palindrome around the central G. The homology present between each of the other D sequences and the 13-mer is also indicated by underlining. The homology between H76 and M173-II D sequences is indicated by double underlining.

kilobases. This indicates that some of the two or more copies of chromosome 12 [some T cells are polyploid (H.v.B. and W.H., unpublished)] in these T cells have undergone sequence rearrangement involving the 6.4-kilobase embryonic fragment. In one cytolytic T-cell clone, D.FL. 4, and one thymoma, WC2, no 6.4-kilobase embryonic fragment was observed. The presence of two non-embryonic bands, of 5.5 and 5.3 kilobases, in D.FL.4 suggests that sequence rearrangement has occurred on both (assuming diploidy) chromosomal copies in different ways. In contrast, WC2 seems to contain only one copy of the 6.4-kilobase sequence and sequence rearrangement has occurred in this fragment. Thus, we have observed sequence rearrangement in 8 out of 13 cytolytic T-cell or thymoma clones. In the majority, rearrangement occurred only in some but not all of the copies of chromosome 12. The sizes of the rearranged fragments seem to fall into three categories—5.5, 5.3 and 4.0 kilobases.

Two DNA clones from two cytolytic T cells

We chose B6.1 and C.SP2 for further studies and cloned the rearranged DNA fragments of 5.5 and 5.3 kilobases, respectively, using a λ WES vector²⁰; we refer to these fragments as B6B1 (short-term B6) and SP2B1 (short-term SP2), respectively. Electron microscopic examination of the heteroduplex molecules formed between either of these T-cell DNA clones and the 6.4-kilobase embryonic *Eco*RI fragment (clone ME183-8) allowed mapping of the recombination sites. The B6 and embryo DNA fragments gave a single-stranded DNA loop flanked by double-stranded DNA arms (Fig. 2a). In contrast, the SP2 and embryo DNA fragments gave Y-shaped heteroduplexes. Measurement of the various parts of the heteroduplex molecules indicated that the B6 DNA fragment has undergone a 1.2-kilobase deletion in a region immediately adjacent (5' side) to the J_{H2} sequence. In contrast, the entire sequence 5' to J_{H3} is

Fig. 1 *a*, Hybridization of T-cell and thymoma DNA with the J_H probe. High molecular weight DNA was prepared from various cloned cytolytic T cells and thymomas by the procedure described previously²⁹, digested to completion with *EcoRI*, and fractionated on 0.8% agarose gel by electrophoresis. The DNA was denatured and transferred *in situ* to nitrocellulose filters (Schleicher and Schuell, BA85) essentially as described previously³⁰. The filters were incubated for hybridization with nick-translated J_H probe (1.1-kilobase *SacI-EcoRI* fragment indicated in Fig. 3A) according to the published procedures². Characteristics of the various cytolytic cells have been described previously^{31,32}. C.SP.2 and C.FL.1 are derived from C3H, B6.1 from C57BL/6, DAS 1 from AKR/DBA F1, all D.FL clones from DBA, and thymomas were all derived from AKR. For comparison, DNA from BALB/c embryos and kidneys of C3H, C57BL/6, AKR and DBA were also analysed. These DNA are indicated by strain names. Numbers and arrows to the left indicate sizes of DNA fragments in kilobases (kb). *b*, Hybridization of BALB/c embryo and C3H kidney DNA with SP2D-J probe. A nitrocellulose filter, prepared as described for *a*, was incubated with the nick-translated SP2D-J probe, 0.8-kilobase *BglII-HindIII* fragment indicated in Fig. 3C. The sizes of the BALB/c DNA fragments detected are shown in kilobases. The 3.8-, 3.6- and 2.8-kilobase bands could be seen in the original autoradiogram, but are too faint to be reproduced.

replaced with a sequence of unknown origin in the SP2 DNA fragment. The points of sequence divergence between the T and embryo cell DNA fragments were further determined by comparison of restriction enzyme cleavage sites (Fig. 3A-C). The results confirm the conclusion drawn by heteroduplex mapping.

The SP2 fragment contains a joined D-J DNA segment

We determined the DNA sequence of the 0.8-kilobase *BglII-HindIII* fragment (Fig. 3Ca) of the SP2 fragment containing the site of recombination according to the strategy shown in Fig. 3Cb. This sequence was aligned with the previously determined sequence of the embryonic fragment in the J_H -coding region (Fig. 4). As suggested by the heteroduplex molecules (Fig. 2b) and the restriction enzyme maps (Fig. 3A, C), the sequences of the two DNA fragments match well starting with the first base of the Phe codon TTT located in the 5' edge of the J_H DNA segment. On the SP2 fragment the Phe codon is preceded by an Asn codon, AAC, which is in turn preceded by a nonamer, TACTATGGT, that codes for a trimeric peptide, Tyr-Tyr-Gly, when read in phase with the J_H . This nonameric nucleotide sequence or its close variants appear in the D regions of seven out of eight myeloma V_H genes sequenced to date (Table 1). Furthermore, the trimeric peptide, Tyr-Tyr-Gly, encoded by the nonamer has been found in the D regions of a majority of myeloma V regions for which amino acid sequence data are available¹¹. These data strongly suggest that a D DNA segment is joined with the J_H sequence on the SP2 fragment.

Further evidence for this notion comes from the feature of the nucleotide sequence located immediately 5' to the putative D DNA segment on the SP2 fragment. Based on the DNA sequencing analysis of the various germ-line DNA segments, it has been predicted that a nonamer,

GGTTTTTGT
CCTAAAACA

and a palindromic heptamer,

CACAGTG
GTGTCAC

separated by a 12-base pair spacer or closely related variants of these sequences, precedes a germ-line D DNA segment^{7,8}. As shown in Fig. 4, the putative D segment joined with the J_H on the SP2 fragment is preceded by two sequences,

GATTTTTGT and TACTGTG
CTAAAACA ATGACAC

separated by a 12-base pair spacer. These results partially fulfill

the predictions of the 12/23-base pair spacer model^{7,8}, and in turn support the conclusion that the sequence joined with the J_H on the SP2 fragment is indeed a D DNA segment. We refer to this D DNA segment as $D_{SP2.1}$.

No V_H -D- J_H joining on the SP2 fragment

Is a germ-line V_H DNA segment also joined on the SP2 fragment? A visual inspection of the SP2 DNA sequence in the region preceding the $D_{SP2.1}$ segment indicates that no germ-line V_H or V_H -like sequence is attached to the D DNA segment. First, there are one, two or four translation termination codon(s) in the three different reading frames of the 300-base pair (an approximate size of a germ-line V_H segment) region 5' to the $D_{SP2.1}$ segment. Thus, this region cannot constitute part of a

Fig. 2 Heteroduplex molecules formed between cloned DNA fragments. Cloned DNA was digested with *EcoRI* and examined under an electron microscope as described previously². Thick arrows indicate points at which heteroduplexes branch out. The numbers indicate lengths of various parts of the molecules in kilobases. In this experiment we used clone ME184-8 instead of MEP203^{6,7} as a source of the 6.4-kilobase embryonic *EcoRI* fragment. Clone ME184-8 was prepared by Richard Maki and contains, in a phage vector, λ_{WES} , the 6.4-kilobase *EcoRI* fragment carrying the four J_H DNA segments. *a*, 6.4-kilobase ME184-8 (J in short-form) versus 5.3-kilobase B6B1 (B6); *b*, 6.4-kilobase ME184-8 (J) versus 5.5-kilobase SP2B1 (SP2); *c*, 5.5-kilobase SP2B1 (SP2) versus 5.0-kilobase C3H-2 (C3H).

germ-line V_H DNA segment. Second, some amino acid residues are highly conserved among the V_H regions. In particular, Cys residues are invariably present in all species studied to date at positions 22 and 92 and are the only Cys residues in the V_H region¹⁰. These two Cys residues play an important part in folding the protein domains through a disulphide linkage^{21,22}. In addition, the Trp at position 36 is invariant across species¹¹. The 300-base pair SP2 DNA sequence preceding the $D_{SP2.1}$ segment contains three Cys and one Trp codons in the frame defined by the J_{H3} peptide. Eight Cys and four Trp codons, and four Cys and one Trp codons, respectively, exist in the other two reading frames. Thus, in all cases the total number of Cys codons is incompatible with the notion that the DNA sequence before the D DNA segment comprises a V_H DNA segment. Furthermore, the locations of Cys and Trp codons within this DNA sequence bear no resemblance to those in a V_H DNA segment. We conclude that no V_H or V_H -like DNA segment is joined with the $D-J_H$ DNA on the SP2 fragment.

Identification of a $D_{SP2.1}$ -like D DNA segment in a germ-line genome

Identification of a $D-J_H$ joining in the DNA of a cytolytic T-cell clone allowed the identification, cloning and characterization of germ-line D DNA segments. We dissected out the 0.8-kilobase *Bgl*II-*Hind*III fragment (Fig. 3C) from the SP2 clone and used it as a hybridization probe (SP2DJ probe) for analysis of *Eco*RI-digested total DNAs of both BALB/c and C3H embryos (Fig. 1b). As this probe contains the J_{H3} and its 3'-flanking sequence, it detects the 6.4-kilobase embryonic *Eco*RI fragment carrying

Fig. 3 Restriction enzyme cleavage maps of the *Eco*RI inserts of various DNA clones. **A**, The 6.4-kilobase *Eco*RI fragment of MEP203^{6,7}; **B**, B6B1; **C**, SP2B1; **D**, C3H-2. Clone MEP203, which was described previously^{6,7}, is an embryonic DNA clone and contains three *Eco*RI fragments, one of which is the 6.4-kilobase fragment carrying the four J_H segments. Cleavage sites were determined by single and double digestions of the cloned DNA by various restriction enzymes. Homologous regions are indicated by bars of two types of shading. The broken lines in **B** indicate the 0.6-kilobase region that appeared as a deletion loop in the heteroduplex molecules formed between the SP2B1 and C3H-2 fragments. The filled boxes correspond to the four J_H DNA segments previously identified on the MEP203 6.4-kilobase fragment^{6,7}. The open boxes are D segments identified by DNA sequencing. Sequencing strategy and finer restriction maps of the 0.8-kilobase *Bgl*II-*Hind*III fragment from SP2B1 and the 0.85-kilobase *Bgl*II-*Hind*III fragment from C3H-2 are shown in **Cb** and **Dd**, respectively. Horizontal arrows indicate the directions and extent of sequencing. The sequence across the 1.2-kilobase deletion of the B6B1 fragment was determined using the *Xba*I-*Bam*HI fragment (**B**). The J_H probe used in Fig. 1a and the SP2DJ probe used in Fig. 1b are indicated in **A** and **Ca**, respectively. Abbreviations used are: E, *Eco*RI; B, *Bam*HI; H, *Hind*III; BgI, *Bgl*II; X, *Xba*I; Xh, *Xho*I; S, *Sac*I; BgII, *Bgl*II; D, *Dde*I; A, *Acl*I; kbp, kilobase pairs; bp, base pairs.

the four germ-line J_H segments. In addition, the probe detected one (5.0 kilobase), four (18, 6.7, 5.4 and 5.2 kilobase) and three (3.8, 3.6 and 2.8 kilobase) bands of high, medium and low intensity, respectively, in BALB/c DNA. A similar, but distinctive hybridization pattern was obtained in C3H DNA. These results may indicate that a number of $D_{SP2.1}$ or $D_{SP2.1}$ -like DNA segments exist in the germ-line genomes of mice, some of which are polymorphic.

We have cloned most of these DNA segments in phage λ vectors and determined their structure and organization in the germ-line genome (Y.K., unpublished). Some characteristics of one of the most prominent fragments, that of 5.0 kilobases (clone C3H-2, C3H in short-term) isolated from C3H embryos, are described here. The heteroduplex formed between clone C3H-2 and the SP2 fragment (Fig. 2c) and the restriction enzyme maps (Fig. 3C, D) indicate that the two DNA fragments are extensively homologous in the 3.6-kilobase region which starts with the 5' *Eco*RI end and ends somewhere near the position of $D_{SP2.1}$ on the SP2 fragment. However, that the homology is imperfect is clearly shown by the presence of a 0.6-kilobase insert (or deletion) in the C3H (or SP2) clone. Nevertheless, the above result suggests that the clone C3H may contain a $D_{SP2.1}$ -like DNA segment at the 3' edge of the homology. We therefore prepared a finer restriction map around this region and determined the entire DNA sequence of the 0.85-kilobase *Bgl*II-*Bgl*II fragment, according to the strategy shown in Fig. 3Db.

As predicted, the sequence homology between the SP2 and C3H fragments is extensive, starting with the 5'-*Bgl*II site and ending with the triplet AAC, the last codon of $D_{SP2.1}$ on the SP2 fragment (Fig. 4). There are 28 single-base substitutions or deletions (or insertions) in the 485-base pair homology region, two of which are within the D DNA segments. The D DNA segment on the embryonic clone C3H is flanked by two sets of the putative recognition sequences with 12-base pair spacers. This confirms the universality of the 12/23-base pair spacer model^{7,8}. Although the C3H-2 D DNA segment and $D_{SP2.1}$ are highly homologous, the imperfectness of the homology in the 5'-flanking regions as well as in the coding segments themselves clearly indicate that they are two different copies of the D segments that occupy independent positions in the germ-line genome. We therefore refer to the C3H-2 D DNA segment as $D_{SP2.2}$.

The B6 fragment contains another joined D-J sequence

Figure 5 shows the sequence across the 1.2-kilobase deletion of the B6 fragment and sequences of the embryonic fragment that cover the 5' and 3' boundaries of the deletion. The sequence homology between the B6 and the embryonic fragments ends with the C-G base pair immediately to the left of the line Ld and resumes with a T-A base pair immediately to the right of line Rd. The latter base pair corresponds to the second letter of the Phe codon TTT located near the 5' terminus of the previously identified J_{H2} sequence^{7,8}. The single base pair C-G present on the B6 fragment and flanked by the two lines, Ld and Rd, is unaccounted for by the embryonic sequence (see below). Ld is preceded by a putative enzyme recognition sequence,

GGTTTTGAC (12-base pair spacer) CACAGTG
CCAAAAC TGTCAC

both on the B6 and MEP203 fragments. On the latter fragment Ld is followed by nine base pairs, which are in turn followed by another putative signal sequence,

CACGGTG (12-base pair spacer) ACAAAAACC
GTGCCAC TGTTTTTGG

Thus, the 9-base pair sequence on the MEP203 fragment fulfills the requirement imposed on a D DNA segment by the 12/23-base pair spacer rule^{7,8}. We therefore conclude that the B6 deletion is due to the joining of the J_{H2} sequence with a D DNA

Fig. 4 Nucleotide sequences of three DNA clones: C3H-2, SP2B1 and MEP203 (refs 6, 7). All sequences were determined by the method of Maxam and Gilbert³³. The sequence of the 0.85-kilobase *Bgl*III–*Bgl*III fragment of clone C3H-2 is aligned for the maximal homology with the sequence of the 0.8-kilobase *Bgl*III–*Hind*III fragment of clone SP2B1. Also aligned with the SP2B1 sequence is the sequence of the *J*_{H3}-containing region of clone MEP203, which was determined previously in our laboratory⁷. The SP2B1 fragment contains a D segment (*D*_{SP2.1}) fused with the *J*_{H3} segment. Amino acid residues encoded by the fused *D*_{SP2.1} and *J*_{H3} on the SP2B1 fragment and those by the unfused *J*_{H3} on the MEP203, numbered according to Kabat *et al.*¹¹, are indicated in italics. The SP2B1 sequence is extensively homologous to the C3H-2 sequence from the 5' *Bgl*III site to the *D*_{SP2.1}–*J*_{H2} boundary, where the homology switches to the MEP203 sequence. The dots and dashes indicate base substitutions and deletions within the homologous regions. The putative recognition sequences for recombinations are boxed. C3H-2 contains a D segment, *D*_{SP2.2}.

segment located 1.2 kilobases upstream. This D DNA segment has been independently identified during analysis of a rearranged fragment isolated from myeloma QUPC52 and is therefore referred to as *D*_{Q52} (see the accompanying article¹⁹).

As mentioned above, one base pair, C·G, is inserted on the B6 fragment at the site of recombination. Based on repeated sequencing of the relevant region, we believe that error is unlikely. This suggested the possible involvement of an intermediate recombination, the extra base pair arising from an independent D DNA segment. However, as described in the accompanying article, no additional D sequence has been identified between *D*_{Q52} and *J*_{H2}. Thus, if one is to pursue this possibility, it is necessary to invoke a scheme that allows joinings of multiple D DNA segments, the order of which in the assembled gene is independent of that in the germ-line genome. Although such a scheme is possible, one alternative is that the act of recombination introduced the extra base pair at the site of joining.

Structure and diversity of D sequences

In the digest of BALB/c mouse embryo DNA (Fig. 1b) the SP2D probe detected at least eight *Eco*RI fragments, each of which is likely to contain at least one copy of a *D*_{SP2.1}-like DNA segment. For the 5.0-kilobase fragment, this was demonstrated directly by DNA sequencing, which led to the identification of *D*_{SP2.2}. Our recent result indicates that the 5.0-kilobase band contains three *Eco*RI fragments each of which hybridizes with the SP2DJ probe (Y.K., unpublished). Thus, assuming that positive hybridization with the probe signifies the presence of at least one D segment, the minimum number of *D*_{SP2.1}-like segments is 10 (8 bands, of which one is triple).

If *D*_{SP2.1}-like DNA segments are abundant, as the Southern gel blot suggests, this is in agreement with the frequent appearance of the *D*_{SP2.1}-like sequences in the D regions of the

assembled V genes. The D-coding regions of seven out of eight assembled *V*_H genes sequenced to date contain a palindromic 13-mer, TACTACGGTAGTA (ref. 8), or its variants (Table 1). The *D*_{SP2.1} and *D*_{SP2.2} also contain sequences similar to the 13-mer (Fig. 4, Table 1). In addition, the D regions of most mouse *V*_H regions for which amino acid sequences are available contain a tripeptide Tyr-Tyr-Gly that is encoded by the *D*_{SP2.1} and *D*_{SP2.2} segments¹¹. Even the *D*_{Q52} segment which did not cross-hybridize with the *D*_{SP2.1}-like segments (Y.K., unpublished) shows significant homology, not only in the coding region (Table 1), but also in the flanking regions (Figs 4, 5). Thus, many, if not all D segments are related to the *D*_{SP2} segments, both evolutionarily and structurally.

Many D regions have extensions on one or both side(s) of the 13-mer (Table 1). The only striking characteristic of the sequences within these extensions is that the 3' extension of the M173-II region shares a heptamer, CGGGGGT, with the H76 D region, the only D region apparently having no homology with the core 13-mer (Table 1). Each of these D regions may be encoded by its own D segment. Alternatively, some D regions, particularly those with relatively long extensions, may be encoded in two or more discrete D segments which are joined in the complete V genes. Two observations argue for the presence of D–D joinings. First, one and four base pairs at the presumed *D*_{Q52}–*J*_{H2} joining sites of the B6B1 and Q52 clones were in fact encoded neither by the *D*_{Q52} nor *J*_{H2} DNA segment (ref. 19 and Fig. 5). Second, we have been unable to detect a *D*_{M141} band in Southern gel blots of embryo DNA when this sequence of 44 base pairs (Table 1) was dissected out from the complete *V*_{M141} gene and used as the hybridization probe. In the same hybridization conditions the *J*_{H4} band was easily detected using the corresponding probe of nearly the same length (H.S., unpublished). If D–D joinings indeed occur, we predict that some D segments carry putative recognition sequences with 23-base pair spacers on at least one side.

Fig. 5 Nucleotide sequences of the recombination regions of clone MEP203 and clone B6B1. The sequence across the 1.2-kilobase deletion of the B6B1 clone is compared with the two sequences of the embryonic fragment, MEP203, that cover the 5' (top)¹⁹ and the 3' (bottom)⁷ boundaries of the deleted segment. The two vertical lines, Ld and Rd, designate the left (5' side) and the right (3' side) boundaries of the deletion as determined by DNA sequencing, respectively. The other markings are as in Fig. 4.

Somatic diversification of heavy chains by V_H-D-J_H joinings

Amino acid sequence data¹² strongly suggest that the three types of germ-line V gene segments, V_H, D and J_H, combine in various, albeit not all possible, combinations to form complete V genes that are active in myelomas and presumably in B lymphocytes. The presence of the common 'recognition' sequences on the joining ends of all three gene segments supports this 'random' assortment. Furthermore, in both κ light- and heavy-chain genes it has been established that a given J DNA segment can assort with different V DNA segments^{4,5,23}.

Another somatic mechanism that might be used to amplify the coding capacity of immunoglobulin genes has been previously suggested by us⁴ and by Max *et al.*⁵, based on a proposed flexibility in the joining enzyme(s) with respect to the exact recombination sites on a given pair of joining gene segments. Although several previous observations in the κ -gene system support this hypothesis^{4,5,7,24,25}, none of the previous studies provides direct evidence for the hypothesis, because no two joinings examined took place between the same pair of gene segments. The present study, when combined with that described in the accompanying paper¹⁹, presents such a case. Thus, the D-J joinings observed in myeloma QUPC52 and T-cell B6 both used the D_{Q52} and J_{H2}, and yet the exact recombination sites differ both on the D and J sides in the two joinings as shown below,

where the arrows indicate the recombination sites and the underlined sequences are the palindromic heptamers. Provided that these recombinants represent the intermediates of successful V-D-J joinings, we can conclude that modulation of exact recombination sites is another source of antibody diversity that is generated somatically.

T-cell antigen receptors are not encoded in assembled V_H, D and J_H segments

Our gel-blotting experiments using the J_H hybridization probe demonstrated that the DNA sequences are often, but perhaps more importantly not always, rearranged in the vicinity of the J_H cluster in various clones of cytolytic T cells and in thymomas. Two other groups reported similar findings and implicated them in the somatic formation of the complete structural genes coding for the antigen receptors of T cells^{17,18}. The present results clearly rule out such a simple interpretation of the gel-blotting experiments. The recombinations in both SP2 and B6 cells involve D and J sequences, but no V_H sequence. In fact, neither recombinant can code for a V-like polypeptide chain in the region located 5' to the recombination sites. We also emphasize that the recombination does not always occur among T-cell clones; we observed no indication of rearrangement around the J_H cluster in four well characterized clones of functional cytolytic T cells. We thus conclude that if the V_H DNA pool is shared by T and B cells to encode the antigen receptors, the four J_H segments identified to date are not used for rearrangement, at least in cytolytic T cells. It may be that T-cell receptors are encoded in an entirely different set of genes, or alternatively T and B cells share the same or an overlapping set of germ-line V_H genes, and another set of J-like and C-like DNA segments exists elsewhere in the genome, with which a V DNA segment joins specifically in T cells. Why, then, are there D-J_H joinings in T cells? One possibility is that they occurred in the common precursor cell which gave rise to B and T cells and have no active role in T-cell function. As discussed in the accompanying article¹⁹, D-J_H joinings might be common on the unexpressed copy of chromosome 12 in myelomas, and one recent study²⁶ suggests that this might also be the case in natural B lymphocytes. Alternatively, the hypothetical T-cell recombinase may mediate these joinings due to lack of absolute specificity for the gene segments encoding the T-cell receptors.

A lower limit for the birth rate of pulsars

Ramesh Narayan & M. Vivekanand

Raman Research Institute, Bangalore-560080, India

Using experimental data on observed pulsars, we have estimated a lower limit for the birth rate of pulsars in our Galaxy to be $B_{1b} = 0.0111 (\pm 0.0050) K$ pulsars yr^{-1} , where K , the 'beam factor', allows for the possibility that only a fraction of all pulsars is beamed towards the Earth. If we take K to be 5, we obtain a mean birth rate of 1 pulsar per 18 yr while we can place a firmer lower bound with 95% confidence of 1 per 50 yr. Two important new features of the present approach are: (1) we do not assume any model for pulsars; (2) we have allowed for selection effects (in a model independent way). Apart from obtaining a more reliable number for the birth rate of pulsars, we conclude that the quantity $P/(2\dot{P})$, where P is the period of the pulsar and $\dot{P}$ is its time derivative, is probably a good measure of age in 'young' pulsars up to half a million years old, and that selection effects which have been neglected in all earlier calculations are significant. The present calculation reduces the discrepancy between pulsar and supernova birth rates.

We assume that $\dot{P}$ is always positive and that the pulsar distribution in the Galaxy is in a steady state. Let $\rho_i(P, \dot{P}, L) dP d\dot{P} dL$ be the density distribution of pulsars in the Galaxy, where L is the intrinsic pulsar radio luminosity. The distribution $\rho_o(P, \dot{P}, L)$ of pulsars observable from the Earth is then given by

$$\rho_i(P, \dot{P}, L) = KS(L)\rho_o(P, \dot{P}, L) \quad (1)$$

where the scale factor $S(L)$ is the ratio of the total volume of the Galaxy to the volume covered in pulsar searches, both weighted by the known radial density distribution of pulsars in the Galaxy. K is assumed to be independent of P , $\dot{P}$ and L and to have a value¹ 5. Now, the flux or current of pulsars at any period P moving from lower to higher periods is given by

$$\begin{aligned} f(P) &= \int_0^\infty \int_0^\infty \rho_i(P, \dot{P}, L) \dot{P} d\dot{P} dL \\ &= K \int_0^\infty \int_0^\infty S(L) \rho_o(P, \dot{P}, L) \dot{P} d\dot{P} dL \end{aligned} \quad (2)$$

Clearly, $f(P)$ is equal to the number of pulsars being born per unit time in the period $0-P$, minus those dying in the same range. Therefore, $f(P)$ is rigorously less than or equal to the total birth rate B . For better statistics, we consider the following average of $f(P)$

$$F(P_{\max}) = \frac{1}{P_{\max}} \int_0^{P_{\max}} f(P) dP \leq B \quad (3)$$

where the rigorous inequality is obviously true for all values of $P_{\max}$.

We have estimated $F(P_{\max})$ by means of equation (4) using experimental data available for 210 pulsars detected by the Jodrell Bank², Arecibo³ and Second Molonglo⁴ surveys above their quoted minimum flux sensitivities:

$$F_{\text{mean}}(P_{\max}) = \frac{K}{P_{\max}} \sum_i S(L_i) \dot{P}_i; \quad 0 < P_i \leq P_{\max} \quad (4)$$

The quantities $S(L_i)$ were computed using published experimental details regarding sky coverage, receiver temperature, and so on of the above three surveys. As a check on our values of

$S(L_i)$, we have calculated the total number ($\pm$ standard deviation) of pulsars in the Galaxy to be

$$N = K \sum_i S(L_i) = 6.05 (\pm 1.88) \times 10^5 \text{ pulsars} \quad (5)$$

From a careful statistical analysis we have also obtained a lower limit N_{951b} with 95% confidence to be 3.19×10^5 pulsars. These numbers are in good agreement with the standard quoted value^{1,5} of 5×10^5 pulsars. Using equation (4), we have calculated $F_{\text{mean}}(P_{\max})$ and also $F_{951b}(P_{\max})$ at various values of $P_{\max}$ (the solid and dashed lines in Fig. 1). By equation (3), any value of $P_{\max}$ can be selected to set a lower bound on B . However, F_{mean} is sensitive to statistical fluctuations arising from individual pulsars whereas F_{951b} is relatively unaffected. We have therefore selected the $P_{\max}$ at which F_{951b} is maximum. Thus

$$\begin{aligned} B_{1b} &= F_{\text{mean}}(1.3 \text{ s}) \\ &= 0.0555 (\pm 0.0248) \text{ pulsars per yr per Galaxy} \\ &= 1 \text{ pulsar in } 18_{-6}^{+15} \text{ yr} \end{aligned} \quad (6)$$

$$\begin{aligned} B_{951b} &= 0.0200 \text{ pulsars per yr per Galaxy} \\ &= 1 \text{ pulsar per 50 yr} \end{aligned}$$

The present calculation has two distinct advantages over earlier approaches.

All earlier attempts to estimate B assume^{1,2} that the age τ of a pulsar is given by the quantity $P/(2\dot{P})$. This relation implies that pulsars slow down because of magnetic dipole radiation⁶ and that the magnetic field does not decay. Our calculation has no such model dependent assumptions. However, we have also developed a variant of the τ calculation⁷ using our concept of pulsar current and individual scales, $S(L_i)$. This gives a B_{1b} of 1 pulsar per 27_{-9}^{+29} yr and a B_{951b} of 1 pulsar per 84 yr. From the approximate agreement of these numbers with our rigorous results in equation (6) we conclude that $P/(2\dot{P})$ is a reasonable measure of pulsar age up to about half a million years, thus setting a lower limit on the decay time of the magnetic field.

This is the first calculation to allow for any selection effects which might arise from pulsar luminosities being correlated with P or $\dot{P}$. Such correlations have been neglected in earlier calculations in spite of there being some evidence⁸ for them. To assess the significance of selection effects, we have computed B_{1b} using equation (4) with a single average scale factor $\langle S(L) \rangle$ for all pulsars⁷, thus in essence neglecting correlations between L and P or $\dot{P}$. We then obtain a birth rate of 1 pulsar per

Fig. 1 The solid line shows $F_{\text{mean}}(P_{\max})$ while the dashed line shows $F_{951b}(P_{\max})$. We have selected the values at $P_{\max} = 1.3$ s to estimate pulsar birth rate.

$6.9^{+1.8}_{-1.2}$ yr. From a statistical comparison of this result with that given in equation (6) we can state with greater than 95% confidence that selection effects are significant and cannot be neglected in birth rate calculations. This throws all earlier calculations into doubt.

The present estimate of pulsar birth rate reduces but does not solve a fundamental problem on the origin of pulsars¹. The birth rate of supernovae, commonly believed to be the progenitors of pulsars, has lagged far behind pulsar birth rates, typical estimates ranging from 1 supernova per 50 yr to 1 per 150 yr (ref. 1). Our pulsar birth rate in equation (6) is significantly lower than earlier estimates, which are typically 1 pulsar per 7 yr but has not completely bridged the gap.

After submitting this work we received a preprint by E. S. Phinney and R. D. Blandford in which the concept of a current in the PP diagram has been used to test pulsar evolutionary models.

We thank J. H. Taylor for his comments and, in particular, for pointing out the importance of selection effects. We also thank R. Nityananda for helpful discussions.

Since the discovery¹ of a 283-s pulsation of an X-ray binary Vela X-1, several observations^{2–8} between 1975 and 1978 have revealed that its pulse period P was decreasing with an average value of $\dot{P}/P \approx -1.5 \times 10^{-4} \text{ yr}^{-1}$. The long-term spin-up which is considered to be caused by the angular torque of accreting matter, is a common feature of X-ray pulsars. The pulse periods of Vela X-1 were measured by the Japanese satellite Hakucho in March 1979 and March 1980, and the period in the latter was found to be significantly greater than in the earlier period despite the general spin-up between early 1976 and early 1979. Moreover, we have measured for the first time the spin-down rate $\dot{P}/P = (2.6 \pm 0.2) \times 10^{-3} \text{ yr}^{-1}$ in March 1980. This spin-down phenomenon is of great importance, as it is considered to be a manifestation of the dynamical behaviour caused by the internal structure of a neutron star.

Fig. 1 Doppler delay curve of the Vela X-1 pulse arrival times observed in March 1980 compared with the calculated delay curve for the best-fit eccentric orbit with parameters given in Table 1. The vertical bars are measured delays with the length representing $\pm 1\sigma$ error limits.

Fig. 2 The long-term pulse period history of Vela X-1. The measurements were made with Copernicus and Ariel V (CP and A5)⁶, SAS 3 (S3)^{2,4,7}, COS B (CB)³, OSO 8 (O8)⁵, Balloon (BA)⁸ and Hakucho (HA, present work). The solid line represents a long term spin-up at a rate of $\dot{P}/P = -1.5 \times 10^{-4} \text{ yr}^{-1}$ for guiding eyes. The short solid line attached to the 1980 point indicates the spin-down rate derived from the present observation (see text).

We observed Vela X-1 in 8.1–21.8 March (UT) 1979 and in 5.2–24.0 March (UT) 1980 from Hakucho, with its spin axis detectors in the energy range 1–22 keV. The binary period, the duration of eclipse, the pulse profile and its energy dependence are in good agreement with earlier results. The X-ray flux varied erratically by a factor of four in positive correlation with the softness ratio, which is the ratio of counting rate in the energy range 1–9 keV to that in range 9–22 keV, in addition to the variation associated with the binary phase. The X-ray luminosity observed in March 1980 was $(1-5) \times 10^{35} \text{ erg s}^{-1}$ in the energy range 2–22 keV at the estimated distance of 1.2 kpc, which is comparable with that in the previous observations.

Despite the differences in profile and intensity of each pulse the epoch of the pulse arrival time can always be identified by the sharp minimum of the pulse profile. Its epoch is obtained only within an accuracy of ~ 10 s for each pulse. Utilizing an uninterrupted pulse train consisting of several successive pulses for each satellite orbit improves the accuracy to 3 s. We obtained 35 and 115 epochs of pulses in 1979 and 1980, respectively.

Table 1 Best-fit orbital parameters for Vela X-1

Parameters	SAS 3† November 1978	Hakucho March 1979	Hakucho March 1980
$a_x \sin i (lt-s)$	112.3 ± 0.8	113.4 ± 3.8	114.4 ± 1.3
$f(M) (M_\odot)$	19.0 ± 0.4	19.5 ± 2.1	20.0 ± 0.7
e	0.094 ± 0.005	0.04 ± 0.07	0.091 ± 0.019
ω	$158^\circ \pm 5^\circ$	$182^\circ \pm 26^\circ$	$160^\circ \pm 7^\circ$
$P(s)$	282.7468 ± 0.0004	282.746 ± 0.006	282.7874 ± 0.0014
$\dot{P}$	$(-9 \pm 18) \times 10^{-9} \ddagger$	$(-20 \pm 10) \times 10^{-9}$	$(23.0 \pm 1.8) \times 10^{-9}$
$\tau (JD - 2,440,000)$	$3,823.53 \pm 0.13$	$3,938.4 \pm 0.7$	$4,307.68 \pm 0.18$
$P_{orb} (days)$	$8.9643 \S$	$8.965 \S$	$8.965 \S$

†After Table 1 of ref. 7

‡Corresponding to $\dot{P}/P = (-0.001 \pm 0.002) \text{ yr}^{-1}$.

§Orbital periods are fixed in the fitting.

The epoch of the n th pulse, after correcting for the heliocentric motion of the Earth, is expressed as

$$t_n = t_0 + P_0 n + \frac{1}{2} P_0 \dot{P} n^2 + a_x \sin i F(\theta, \omega, e, \tau)$$

where P_0 is the pulse period at a specified epoch t_0 , $\dot{P}$ is the rate of change of the period, $a_x \sin i$ is the projected semi-major axis of the orbit of the X-ray star, and F represents the effect of an eccentric motion with the periastron longitude ω , the eccentricity e , the time of periastron passage τ , and the mean anomaly $\theta = 2\pi (t - \tau)/P_{orb}$. The orbital period derived from X-ray eclipses between November 1978⁷ and March 1980 is $P_{orb} = 8.965 \pm 0.001$ days. This is considered a fixed parameter for the present analysis. Table 1 shows the orbital parameters obtained by fitting the observed pulse arrival times to the above equation. The best-fit Doppler curve for the data of March 1980 is shown in Fig. 1. All the parameters except P and $\dot{P}$ are consistent with earlier results^{2,3,7}.

Both the increase of the pulse period P between March 1979 and March 1980 and the positive value of $\dot{P}$ in March 1980 are remarkable. In March 1979 $P = 282.745 \pm 0.006$ (1σ)s, which lies nearly on the extrapolated line with $\dot{P}/P = -1.5 \times 10^{-4} \text{ yr}^{-1}$, whereas $P = 282.7874 \pm 0.0014$ (1σ)s in March 1980 which is significantly above this line, as shown in Fig. 2. This appreciable change in P seems to indicate a spin-down of the pulsar within a year. A similar increase of P was observed in late 1975³ and is suspected to be associated with a flare occurring in August 1975⁹. The increase in period observed in March 1980 may also be related to a flare in July 1979 observed by Hakucho¹⁰. Utilizing the data over two orbital cycles in March 1980 we obtain $\dot{P} = (23.0 \pm 1.8) \times 10^{-9}$, or $\dot{P}/P = (2.6 \pm 0.2) \times 10^{-3} \text{ yr}^{-1}$. Thus Vela X-1 occasionally undergoes a spin-down in the course of spin-up over a period of many years.

The observed increase of spin period can hardly be explained by fluctuations in the accretion rate^{11,12}, because the X-ray intensity in March 1980 is essentially the same as it was previously, although the model gives a favourable explanation for the period changes of the fast rotator such as Her X-1 and Cen X-3. Other external mechanisms of torque variation, such as mass ejection from the neutron star or the reversal of accreting stream in the wind-fed accretion, seem to have difficulty in accounting for the observed high rate of change of the pulse period. The internal torque acting on the crust of the neutron star, such as the braking stress of the rotation of crust caused by a lagging fluid core¹³, seems to be a possible explanation of the observed spin-down episode. A detailed consideration of the theoretical treatment of such a problem as well as further observations of the period change will be reported elsewhere.

The very soft X-ray transient H1853+60

Robert A. Stern, Prahlad C. Agrawal*
& Guenter R. Riegler

Jet Propulsion Laboratory, California Institute of Technology,
Pasadena, California 91103, USA

The increased sensitivity, sky coverage and spectral range of X-ray observatories have revealed a wide range of transient phenomena. The 'classical' X-ray transients flare rapidly, sometimes increasing by more than an order of magnitude in X-ray flux in a matter of days, and decay on time scales of months. Such transients are mainly located in the galactic plane, often associated with 'steady' X-ray sources¹. Some high galactic latitude transients, most of which are optically unidentified, have been observed to vary on time scales of tens of seconds to days^{2,3}. Most transient sources have been detected at energies greater than 1 keV; more recently, however, softer X-ray transients have been detected with observations on HEAO 1 and other satellites⁴⁻⁹. We now report detection of a new soft X-ray transient, H1853+60, using data from the low energy detectors (LEDs) on the HEAO 1 A-2 experiment.

H1853+60 was observed by both LEDs 1 and 2 during a series of scans in ecliptic latitude on 13 May 1978 (see ref. 8 for details of the A-2 experiment operation). The source was detected at levels of 5.3 and 6.3 σ above background on two scans by LED 1 in the 0.16–0.4 keV band. There is no evidence for any emission above 0.5 keV. The source detection in LED 2 at the same sky location as LED 1 is significant, since that detector is offset by 6° from LED 1 in the scan plane, providing convincing evidence that the transient was not due to time-dependent particle events or instrumental effects. The source is unresolved by the 1.55° FWHM field of view of LED 1 along the scan direction.

Figure 1 plots the light curve of H1853+60 in the 0.16–0.4 keV band for 30 April–23 May 1978 (days 120–143). The source intensity has been corrected for the LED 1 collimator response (2.95° FWHM) perpendicular to the scan direction, assuming that the true source location is at the centre of the 90% confidence error box shown in Fig. 2. Scans with angular offsets $\geq 1.5^\circ$ from scan plane passing through the error box centre were not included so as to minimize possible systematic errors. Before 10 May, there is no evidence for a steady source (2σ upper limit ≈ 1 c.p.s.); an upper limit to flare-like behaviour is ≤ 3 c.p.s. From 11 to 16 May, the data are inconsistent (probability $\leq 1\%$) with any single count rate, even if we remove the two $\geq 5\sigma$ 'flare' scans. Summing scans together on a day-to-day basis, we also find no evidence for the presence of a source ($\leq 2\sigma$) before 10 May, but there is some ($\sim 3.5\sigma$) indication of post-outburst emission on 14 May; by 15 May the source is gone.

The peak LED 1 count rate on 13 May was 9.3 ± 1.5 c.p.s. above background, corresponding to a broad-band flux of $\sim 3 \times 10^{-11} \text{ erg cm}^{-2} \text{ s}^{-1}$ in the 0.16–0.4 keV band. H1853+60 was not detected in a steady or flaring state 6 months earlier when HEAO 1 scanned the same area of the sky. In addition, no steady source was detected in the HEAO 1 MED or HEDs (2–10 keV band)¹⁰, and an examination of individual MED and

* Permanent address: Tata Institute of Fundamental Research, Bombay, India.

HED scans while H1853+60 was flaring shows no evidence for X-ray emission (F. Marshall, personal communication).

Because of the relatively poor spectral resolution of proportional counters at such low energies, we can only obtain upper limits to the source temperature and interstellar medium column density of $T \leq 10^6$ K and $N_H \leq 10^{20.6} \text{ cm}^{-2}$, respectively. The spectrum does, however, exhibit a steep rise at the lowest detectable energies, suggesting that much of the energy output of the transient event was below our detection threshold of 0.16 keV.

A search for possible optical counterparts for H1853+60 in the available literature has produced the following candidates: the Mira variable AD Dra which is located at the northeastern corner of the error box, the faint (15th magnitude) galaxy MCG+10-27-001, the centre of the Zwicky cluster ZC1851.3+6032, the nearby double star Gliese 725A and B, and a number of 8th and 9th mag SAO stars. There are no previously discovered X-ray sources, Yale catalogue bright stars, RS CVn systems and other variable stars, white dwarfs, or other proper motion or nearby stars in the error box.

Gliese 725AB (dM4, dM4.5; HD173739) has been reported as a flare star¹¹. Although there is no evidence for hydrogen emission—a characteristic usually associated with UV Ceti flare stars—Ca II emission has been observed (this, however, is common in late-type dwarfs)¹². Few X-ray flares from UV Ceti stars have been observed, and those that have been are generally seen at harder (≥ 2 keV) energies than H1853+60 (refs 13, 14). AT Mic, which was detected by both the HEAO 1 LEDs and MED, had a flaring spectrum characterized by $T \geq 10^7$ K (ref. 14). The detection of H1853+60 at $\geq 5\sigma$ for two successive scans separated by 0.1 day is also not consistent with typical UV Ceti flare risetimes¹³. If HD173739 proves to be the optical counterpart of H1853+60, one possibility is that we have observed a 'long-duration enhancement' such as that seen in the solar corona, with risetimes of the order of hours, and decay times of a day or more; even these enhancements, however, have characteristic temperatures only slightly lower ($\sim 3\text{--}7 \times 10^6$ K) than those of a solar flare^{15,16}.

Although the stellar flare hypothesis cannot be definitely ruled out, we must also consider the similarity of H1853+60's spectral and temporal characteristics to several other transients observed by the HEAO 1 LEDs^{8,9}, suggesting a common emission mechanism for these events. As the transients referred to were initially discovered using 1-day superpositions of the LED data, which have been examined extensively (J. Nousek, personal communication), it is unlikely that many more transients as strong as these will be discovered, except on an individual scan basis. The only unusual class of optical object common to the transients' error boxes are Mira variables, of which $\sim 4,500$ are known. Given an error box area of $\sim 1.5 \text{ deg}^2$,

Fig. 1 Light curve of H1853+60 in the 0.16–0.4 keV band. Error bars are $\pm 1\sigma$.

Fig. 2 90% confidence error box for H1853+60; HD173739 = GL725A.

there is $\geq 10\%$ probability that a Mira variable would be found within a typical LED error box by chance alone. (Ref. 8 reviews the possibility of such transient X-ray emission in supernova outbursts, undiscovered RS CVn systems and shock heating of the atmospheres of the Mira variables described above; none of these mechanisms is likely to account for emission in H1853+60.)

The suggestion of a U Gem-like outburst from an as yet undiscovered dwarf nova (also discussed in ref. 8) is intriguing because of the similarity of the spectra observed in both U Gem⁵ and H1853+60, and the approximately equal risetimes for the outbursts. Although U Gem was also observed in harder (2–10 keV) X rays¹⁷, the 0.16–0.4 keV peak flux from H1853+60 is about 10 times less than that from U Gem, and thus if the harder X rays scale proportionately, the hard X-ray flux from such a dwarf nova outburst would fall below the sensitivity level of the MED or HEDs for single scans ($\sim 4\text{--}6 \times 10^{-11} \text{ erg cm}^{-2} \text{ s}^{-1}$). If we assume that H1853+60 is indeed a dwarf nova with the same X-ray luminosity as U Gem, we derive a distance of about three times that of U Gem, or ~ 300 pc, based on usual distance estimates⁵. If the optical outburst is scaled in luminosity, the optical counterpart of H1853+60 would be at $V \sim 12$ at outburst and $V \sim 16$ when quiescent. Although fainter U Gem-type systems have been discovered¹⁸, the completeness of the sample of U Gem stars down to a particular limiting magnitude is unknown; further optical observations will be needed to confirm the dwarf nova hypothesis.

We acknowledge useful discussions with J. Nousek. This work was performed at the Jet Propulsion Laboratory under NASA contract NAS 7-100. P.C.A. is a NAS-NRC Senior Research Fellow.

The Kelvin equation and the capillary condensation of water

L. R. Fisher, R. A. Gamble & J. Middlehurst

CSIRO Division of Food Research, PO Box 52, North Ryde, New South Wales 2113, Australia

The Kelvin equation¹ relates the equilibrium vapour pressure of a liquid to the curvature of the liquid-vapour interface. It predicts that undersaturated vapours will condense in channels of sufficiently small dimensions. While the applicability of the Kelvin equation to organic liquids with meniscus radii as low as 4 nm has been verified by direct experiment², its applicability to water for meniscus radii below 4 nm is unverified, and has been doubted^{3,4}. We have used Fizeau interferometry to measure directly the capillary condensation of water in a wedge between fused silica surfaces. Measurements were made at relative vapour pressures (P/P_s) from 0.996 down to 0.945, corresponding to theoretical meniscus radii from ~120 to 9 nm. We find only a small discrepancy between our experimental results and the Kelvin equation in the vapour pressure range covered, provided that correct account is taken of the effect of the adsorbed film, up to 200 nm thick, on the meniscus shape.

The Kelvin equation forms the basis of critical nucleation theory⁵, and is widely used in the interpretation of such diverse phenomena as adhesion⁶, the enhanced solubility of small particles⁷ and the retention and transport of liquids in porous materials⁸⁻¹⁰. Because water is an important liquid in the above applications, we need direct experimental evidence concerning its capillary condensation behaviour.

Cross and Picknett¹¹ have shown experimentally that water obeys the Kelvin equation for meniscus radii $> \sim 4 \mu\text{m}$, but most applications of the equation involve much smaller radii. Other experiments^{3,4} have purported to show that the Kelvin equation grossly underestimates the degree of capillary condensation of water, but these results are now generally ascribed to the presence of impurities^{4,12}, and there have been no reliable studies in the important region covering menisci with radii $< 1 \mu\text{m}$.

For the present experiments, two silica surfaces (either two optical flats held as a very narrow wedge, or a spherical surface of radius 69 m on a flat surface) were clamped between Teflon supports in an evacuated isothermal enclosure. The vapour pressure in the enclosure was controlled by an aqueous potassium nitrate solution. Stringent cleaning procedures, including prolonged boiling in nitric acid followed by prolonged boiling in freshly distilled water and finally blowing dry with filtered dry nitrogen, were applied to the surfaces.

Each silica surface was first tested for wettability by exposing it to the vapour above warm distilled water and observing the appearance of coloured interference fringes on the surface (the so-called 'steam test')¹³. Surfaces for which the contact angle is non-zero exhibit hazy condensation due to microdroplets, rather than clear, broad fringes. At the end of an experimental run, the silica surfaces were carefully separated so that the condensed liquid collected at one point, where it evaporated. The surfaces were then examined in a strong light to ensure the absence of any residue. This test is sufficiently sensitive to detect dissolved material equivalent to 0.01 of a monolayer. The surfaces were then retested for wettability, and finally atomic absorption spectroscopy was used to test for the presence of inorganic ions (for example, K^+) in a small volume (0.1–0.2 ml) of water rinsed over each surface after each experiment. Only if all these tests were passed was the result of an experiment accepted. Also, no experimental run was accepted unless the same results were obtained with increasing and decreasing relative vapour pressure.

The appearance of capillary-condensed water in a wedge between two optical flats is shown in Fig. 1. The Fizeau fringes are shifted with respect to their position when the surfaces were dry because of the presence of the adsorbed water film. This shift was used to calculate the adsorbed film thickness Z_1 (Table 1). The distance D_{men} between the silica surfaces at the meniscus can then be calculated from the fringe positions in the dry state. The results of condensation experiments for both the wedge and the sphere-on-flat configuration are given in Fig. 2, in which $-\ln(P/P_s)$ is plotted against $1/D_{\text{men}}$.

The finding that water reversibly forms relatively thick adsorbed films on a fused quartz surface agrees with the results of Pashley and Kitchener's¹³ ellipsometric study. These results clearly have a bearing on the question of water 'structure' at solid interfaces^{4,12,13}, but we cannot add any comment to that already made by Pashley and Kitchener who have shown that very thick films are consistent with calculations from double layer repulsion theory. However, several authors have postulated deviations from the Kelvin equation because of the influence of such a thick adsorbed film (more correctly, the influence of a long-range adsorption potential) on meniscus curvature¹⁴⁻¹⁷, and it is with this aspect that we are now concerned.

All authors find the same form for the Kelvin equation for the case of capillary condensation in a slit-shaped pore^{17,18}:

$$D_{\text{men}} = \frac{2\gamma V_m}{R_s T \ln(P/P_s)} + 2Z_1 - \left\{ 2/R_s T \ln(P/P_s) \right\} \int_{Z_1}^{D_{\text{men}}} F(Z) dZ \quad (1)$$

Fig. 1 a, Diagrammatic representation of liquid condensed in wedge between two optical flats. b, Comparison of appearance of wedge, viewed normally in monochromatic light ($\lambda = 546.1 \text{ nm}$) before (right-hand side) and after (left-hand side) exposure to water vapour at $P/P_s = 0.9969$. Note that all fringes have shifted equally, showing that the Laplace pressure in the condensed liquid does not distort the silica surfaces. Silica surfaces are in contact at the bottom of the picture, the bright mark at the top is a gold foil spacer.

Table 1 Experimental adsorbed film thickness Z_1 of water condensed in a wedge between flat silica surfaces

Relative vapour pressure P/P_s	Z_1 (nm)	$-0.43/\ln(P/P_s)$ (nm)
0.90	3*	4.1
0.95	5*	8.9
0.965	8*	12.0
0.98	20, 27*	21
0.9925	(59 ± 5)†	57
0.9944	(82 ± 5)†	77
0.9955	(120 ± 10)†	95
0.9969	(200 ± 30)†	139
1.00 ± 0.001	150*‡	∞

* Data from ref. 13: we obtained agreement with these figures in an experiment where the condensation was reversible, but the results were rejected because of trace quantities of residue at the end of the run.

† Present work.

‡ Agrees with calculations based on double-layer theory.

where γ is the surface tension, V_m the molar volume, P' is the vapour pressure at which the liquid just irreversibly evaporates, Z the normal distance from the solid surface, R_0 the gas constant and T the absolute temperature (this form of the equation neglects corrections which may be necessary at extremely high meniscus curvatures¹⁹). The first term is the simple Kelvin term, the second makes allowance for the adsorbed film by simple subtraction, and the third is a correction factor to allow for the effect of adsorption potential on meniscus curvature. The function $F(Z)$ is the adsorption isotherm of water on a flat surface. The accuracy of the adsorption data does not warrant numerical evaluation of this integral over the whole meniscus, but fortunately the simple expression Z_1 (nm) = $0.43/\ln(P_s/P)$ follows the data sufficiently closely over much of the range of interest, so $F(Z)$ can be put in the form $F(Z) = 0.43R_0T/Z$, the integral of which can be obtained by a simple iterative method¹⁷.

The uncorrected Kelvin equation, the Kelvin equation with allowance for the adsorbed film by simple subtraction, and equation (1) are plotted in Fig. 2. Only equation (1) is in reasonable agreement with the experimental data, although there is still a significant discrepancy. This discrepancy may well be due to the breakdown of the 'boundary layer approximation' implicit in equation (1). That is, it may not be possible to treat

For the sphere-on-flat experiments, values of Z_1 were calculated from Z_1 (nm) = $-0.43/\ln(P/P_s)$.

the adsorption and capillary potentials as strictly additive when Z_1 is of the order of $D_{men}/2$. This point has been discussed in detail elsewhere²⁰. The fact that the difference between theory and experiment apparently decreases with increasing D_{men} supports this interpretation.

We conclude that water reversibly forms relatively thick adsorbed films (up to 200 nm) on fused silica surfaces. The origin of the stability of these films is not yet fully understood¹³. The presence of these films affects the meniscus shape for capillary-condensed water, and this effect accounts almost entirely for the capillary condensation behaviour of water. The small residual difference between theory and experiment may well be a consequence of the breakdown of the 'boundary-layer' approximation used in current theories. A fuller report of this work will be given elsewhere.

Hydrogen production from photolysis of steam adsorbed onto platinized SrTiO₃

R. G. Carr & G. A. Somorjai

Photodissociation of high pressure (1–8 atm) water vapour adsorbed onto the partially platinized surface of single crystal SrTiO₃ has been observed. The reaction is catalytic; several thousands of monolayers of hydrogen have been produced. The reaction requires light of greater than bandgap (3.1 eV) energy, and proceeds vigorously only if elevated temperatures (375–450 K) and high pressures are used. Recombination of products and poisoning of the metal apparently diminishes the reaction rate after several hours. Previous work on this reaction has been done in the presence of an electrolyte, generally at room temperature. The present work is a significant departure from such an environment, and is important because the surface is not contaminated with an electrolyte. The surface is therefore accessible to ultrahigh vacuum surface analytical techniques such as electron spectroscopy, before and after the reaction. From these studies detailed information about the mechanism may be obtained. In addition, the existence of a surface hydrogen species at elevated temperatures allows us to combine water photolysis directly with other catalytic reactions, such as ammonia synthesis with N₂ and methane synthesis with CO or CO₂.

A reaction chamber made of stainless steel was fitted with a sapphire window and placed in the oven of a gas chromatograph. Light from a high-pressure mercury discharge lamp passed through the window and was incident on the surface of the crystal. The intensity was $\sim 10^{16}$ photons $\text{cm}^{-2} \text{s}^{-1}$ in the energy range above the band gap. A single crystal wafer of SrTiO_3 with nominal (111) orientation was rough-polished and coated *in vacuo* with platinum evaporated from a tungsten filament. We used non-conducting, stoichiometric SrTiO_3 as bulk electrical conductivity has little influence on localized surface reactions. The roughness of the surface ensured that it was only partially covered with platinum. The photoreaction rate was highest with a transparent coating of platinum and decreased with heavier, more opaque coatings, which would cover all semiconductor surface sites.

Ultrapure water was admitted into the evacuated cell at the beginning of an experiment, and pumped through a loop which included the cell and an automatic sampling valve, so that gas samples could be withdrawn periodically. A sample was then analysed in the gas chromatograph, which was fitted with a thermal conductivity detector. With argon carrier gas, we could detect 10 monolayers of H_2 easily, and O_2 with about 20 times less sensitivity. The whole system accessible to water vapour was kept at uniform temperature so that high pressures could be achieved. Figure 1 shows the cell design.
